Figure 84-8 Chest radiographic findings of pneumomediastinum. **A**, Frontal chest radiograph shows abnormal lucency interposed between the left cardiac border and left mediastinal pleura (*arrows*) due to the presence of mediastinal gas. Gas outlines the superior mediastinum and extends into the neck as well. **B**, The "continuous diaphragm" sign. Frontal chest radiograph shows a linear gas lucency between the heart and diaphragm (*arrowheads*), rendering the diaphragm visible where it is normally obscured because of contact with the inferior pericardium and heart. **C** and **D**, Chest radiographic findings of pneumomediastinum: "ring-around-the-artery" sign. **C**, Frontal chest radiograph shows few features that allow the confident diagnosis of pneumomediastinum. **D**, Lateral chest radiograph shows gas surrounding and sharply outlining the extrapericardial segment of the right pulmonary artery (*arrowheads*). **E** and **F**, Chest radiographic findings of pneumomediastinum: the "extrapleural air" sign. **E**, Frontal chest radiograph shows gas lucency separating the diaphragm from the combined parietal and visceral pleural layers (*arrowheads*). **F**, Axial chest CT displayed in lung windows shows gas, representing pneumomediastinum outlining both sides of the medial left hemidiaphragm (*arrowheads*). **G**, Chest radiographic findings of pneumomediastinum: Naclerio's "V" sign. Frontal chest radiograph shows lucency extending along the descending thoracic aorta (*arrowheads*) and extending laterally between the parietal pleura and medial left hemidiaphragm, intersecting gas lucency along the latter (*arrows*). Other chest radiographic features of pneumomediastinum, such as sharp outlining of the aortic arch and left mediastinum, are evident. **H**, Chest radiographic findings of pneumomediastinum: elevation of the thymus causing the "thymic spinnaker-sail" sign. Frontal chest radiograph in an infant shows abnormal mediastinal lucency that forms an interface (*arrowheads*) with superior mediastinal tissue, representing the thymus (*T*); note that the gas lucency "elevates" the thymus. **I** and **J**, Frontal and lateral chest radiographs in an older child show gas lucency along the left mediastinum (*arrowheads*) on the frontal projection (**I**), and sharply outlining (*arrowheads*) the thymus (*T*) on the lateral projection (**J**). **K**, Chest radiographic findings of pneumomediastinum: gas in the pulmonary ligament. Frontal chest radiograph shows triangular gas lucency in the retrocardiac area (*arrowheads*), the apex of which points superiorly. This finding resolved on repeat chest radiography 1 week later. (Courtesy Michael Gotway, MD.)

eFigure 84-9 Pneumomediastinum mimics at chest radiography: unusual appearance of a thickened left major (oblique) fissure. **A**, Frontal chest radiograph shows a curvilinear opacity (*arrows*) in the left mid-lung. The lucency between this opacity and the left cardiac border creates the appearance of pneumomediastinum. **B–D**, Axial chest CT displayed in lung windows shows that the left mid-lung opacity is caused by thickening of the left major (oblique) fissure (*arrows*), which is posteriorly rotated due to volume loss in the left lower lobe. (Courtesy Michael Gotway, MD.)

eFigure 84-10 Pneumomediastinum mimics at chest radiography: Mach bands. **A**, Frontal chest radiograph shows prominent lucency along the left cardiac border. No other features of pneumomediastinum are present. **B**, Lateral radiograph reveals no evidence of pneumomediastinum. The finding is due to a Mach band. Mach bands are alternating light and dark lines that are seen at the border between objects of differing contrast, optical density, or luminance, and are created by the process of lateral inhibition in retinal cells. This process effectively results in enhancement of the border between objects with differing optical densities. (Courtesy Michael Gotway, MD.)

eFigure 84-11 Tension pneumomediastinum. A-D, Axial chest CT images displayed in lung windows show a large gas collection with numerous internal loculations in the middle mediastinum (arrowheads) resulting from esophageal perforation. The gas collection exerts significant mass effect on the heart, compressing and distorting the ventricles. Mediastinitis from the esophageal rupture was present, and the mediastinal gas and fluid was decompressed through placement of several thoracostomy tubes followed by repair of the esophageal laceration. LV, left ventricle; RV, right ventricle. (Courtesy Michael Gotway, MD.)

eFigure 84-12 Mediastinal abscess: CT findings. A-D, Axial contrast-enhanced chest CT displayed in soft tissue windows shows an enhancing fluid collection (arrowheads) in the mediastinum, representing an abscess that was seen after attempted dilation of a stricture following esophageal resection and gastric pull-through. E-H, CT images of the percutaneous drainage of the mediastinal abscess. Axial chest CT obtained during percutaneous drainage of the mediastinal abscess shows placement of a coaxial needle (arrow, E) into the anterior margin of the abscess through a paratracheal approach. Subsequent images (F-H) show a wire (double arrows) coiling in the abscess, over which a small drainage catheter was placed. g, intrathoracic stomach following gastric pull-through. (Courtesy Michael Gotway, MD.)

eFigure 84-13 Sternal dehiscence: imaging findings. **A**, Frontal chest radiograph obtained at presentation in a patient complaining of increasing chest pain and tenderness several months after a sternotomy. **B**, Frontal chest radiograph obtained shortly after the sternotomy, prior to symptoms, is shown for comparison. Note migration of sternal wires (*arrows*) on the presentation image (**A**) compared with **B**. **C–F**, Axial unenhanced chest CT shows that the sternal wires have “pulled through” the sternum (*arrows*), resulting in marked widening of the space between the two sternal halves (*arrowhead*). **G**, Coronal unenhanced chest CT shows sternal widening (*arrowheads*). (Courtesy Michael Gotway, MD.)

eFigure 84-14 Mediastinal fibrosis: MR appearance of right peribronchial involvement. Axial T1-weighted spin-echo images before (**A**) and after (**B**) intravenous contrast administration show an enhancing soft tissue mass in the right peribronchial region (*arrows*). **C**, Axial short tau inversion recovery image (a sequence designed to suppress signal from fat and highlight signal from fluid, such as edema; note increased signal in the cerebrospinal fluid posteriorly) shows increased signal within the actively inflamed right peribronchial tissue (*arrow*). Biopsy showed fibrotic material. (Courtesy Michael Gotway, MD.)

INTRODUCTION

Problems with breathing are the root cause of the most common and serious of the sleep disorders. Such breathing problems are associated with a wide range of poor health outcomes including high blood pressure, heart attacks, stroke, diabetes, obesity, and altered brain function. This chapter is structured around several clinically oriented key concepts that relate to understanding the control of breathing and the upper airway during sleep. The key concepts are rooted in basic physiologic principles that are first presented, and these are followed by their application to the spectrum of clinical sleep-related breathing problems. To facilitate understanding of such sleep-related breathing problems further, we present several “perturbations” that importantly impact respiratory function during sleep. We also stress that although each perturbation is defined individually, several such perturbations can coexist in any one person to predispose to respiratory dysfunction. Such respi-

ratory dysfunction can manifest itself either specifically in sleep, or it can be present in wakefulness and made worse by sleep. Ultimately, it is the interaction of these perturbations with mechanisms of respiratory control in sleep that critically impact overall clinical course, stability, and long-term outcome.

WAKEFULNESS AND SLEEP

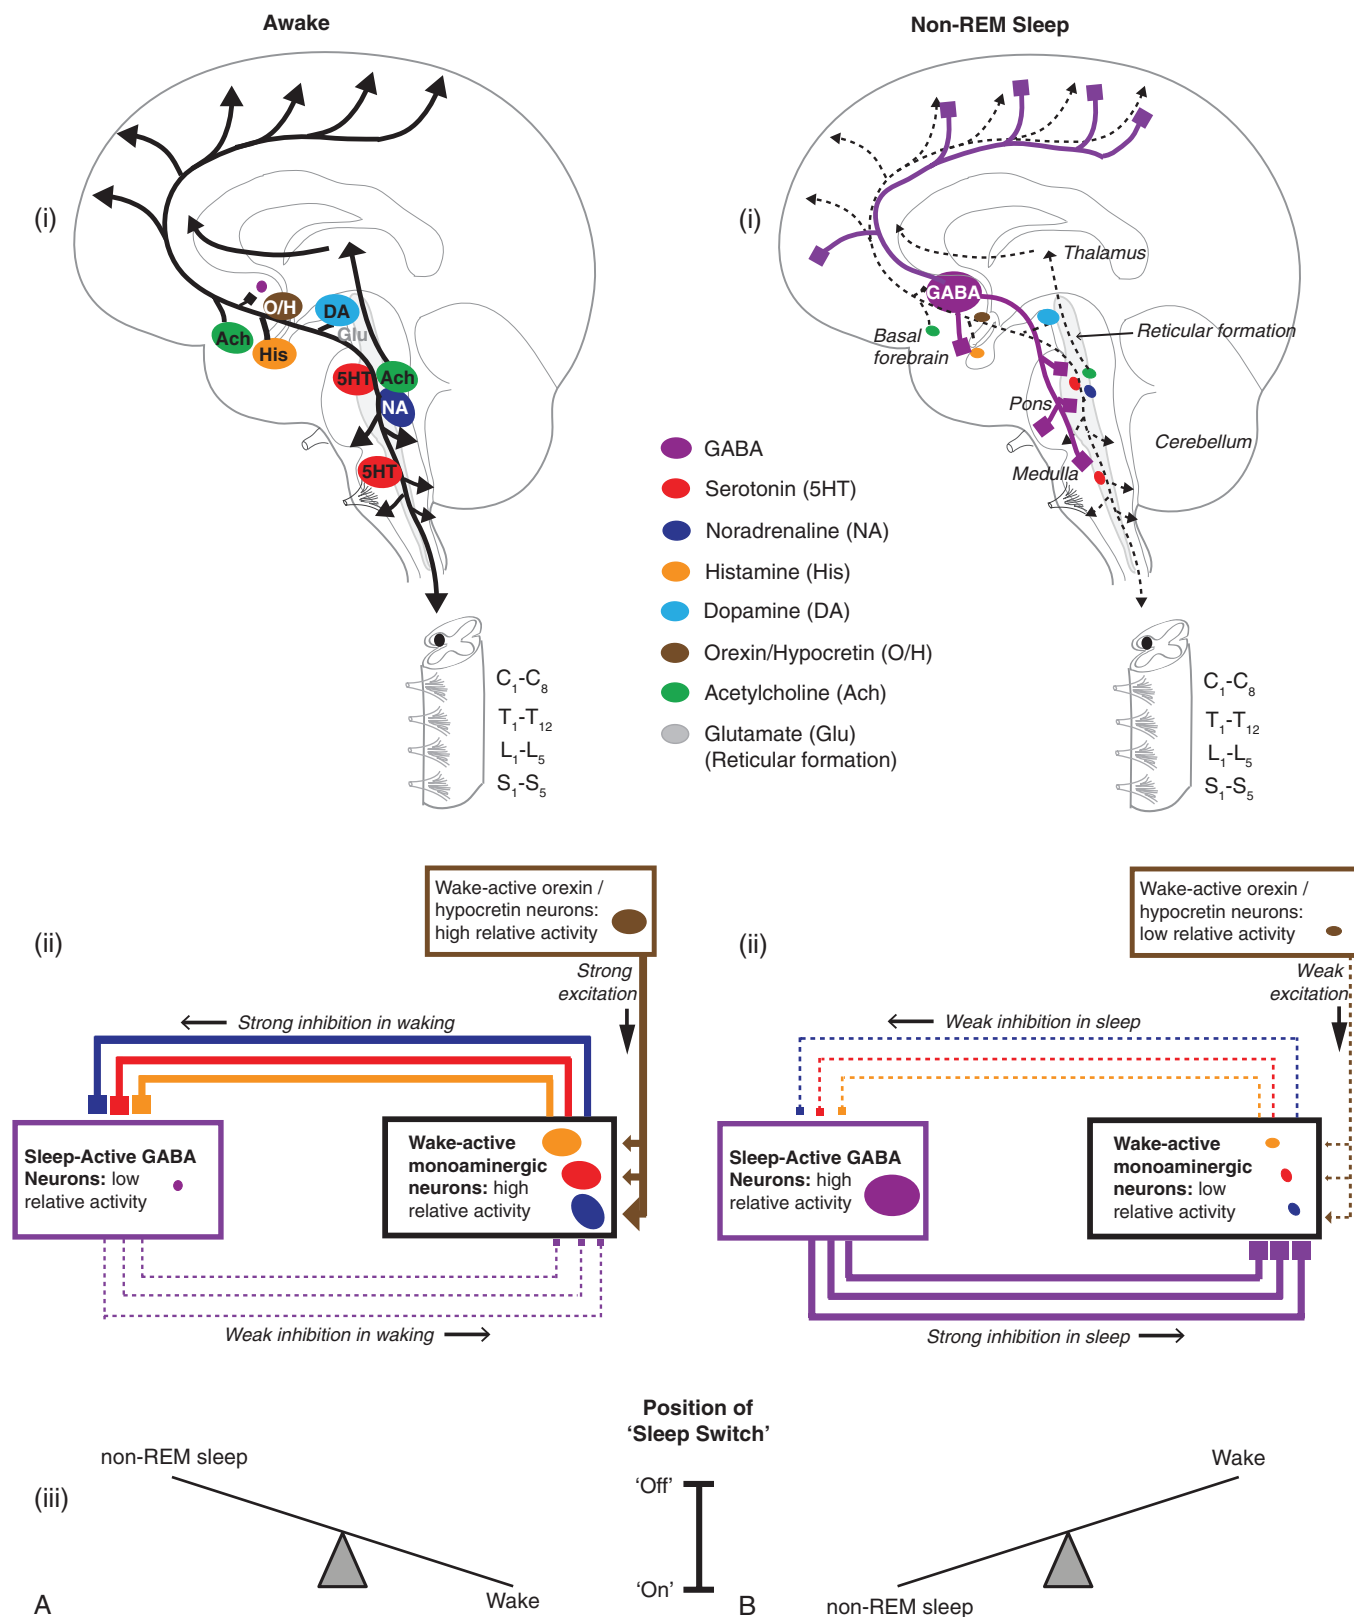

Some of the key brain circuits that generate the states of wakefulness, *non-rapid eye movement* (non-REM) sleep, and REM sleep are summarized in this section. Knowledge of these mechanisms leads to understanding the principle of the “sleep switch.”^{1,2} This principle is then used to explain how the common, serious, and at times life-threatening problems associated with sleep and drug-induced brain sedation and respiratory depression can work through common brain pathways.

GENERATION OF WAKEFULNESS AND SLEEP

Wakefulness

Figure 85-1A illustrates some of the main neuronal clusters involved in the regulation of brain activity in wake-

fulness and sleep. Serotonin, noradrenaline, histamine, dopamine, orexin (also named hypocretin), acetylcholine, and glutamate-containing cell groups collectively contribute to the brain activation of wakefulness. Such brain activation manifests as relatively low-voltage and fast-wave

activity in the *electroencephalogram* (EEG), and resting motor tone in the electromyogram recorded from postural muscles.

Some of the neuronal clusters that significantly contribute to the brain activation of wakefulness include dorsal and caudal raphe neurons located in the pons and medulla, respectively (serotonin-containing); the locus coeruleus (noradrenaline-containing); the tuberomammillary nucleus (histamine-containing); the ventral periaqueductal gray (dopamine-containing); the perifornical region of the lateral hypothalamus (orexin/hypocretin-containing); the pedunculopontine and laterodorsal tegmental nuclei in the pons as well as regions of the basal forebrain (acetylcholine-containing); and several of the aforementioned cell clusters plus distributed neurons in what has been commonly termed the *reticular formation* (glutamate-containing).

Non-REM Sleep

Non-REM sleep is often thought of as the “restorative” nondreaming phase of sleep. It is promoted and sustained by a system of neurons that inhibit the brain-arousal systems of wakefulness (see Fig. 85-1B). The chief cell groups that comprise this non-REM sleep-active inhibitory system include neurons in the ventrolateral preoptic area and anterior region of the hypothalamus, and regions of the basal forebrain. The cell groups that comprise this non-REM sleep-active inhibitory system synthesize and secrete the inhibitory amino acid *gamma-aminobutyric acid* (GABA) and the neuropeptide galanin. GABA is one of the chief inhibitory neurotransmitters in the brain. The direct GABA-mediated inhibition of the brain arousal systems identified in the section “Wakefulness” and Figure 85-1A, in combination with activation of cortically projecting inhibitory GABA neurons (see Fig. 85-1B), is responsible for the relatively higher-voltage and slower-wave EEG activity that typifies non-REM sleep.

REM Sleep

REM sleep, on the other hand, is associated with the dreaming phase of sleep and is accompanied by paralysis (atonia) of the skeletal musculature, effects that can also impact breathing. There are two major circuits involved in REM sleep generation (Fig. 85-2). The activation of these circuits produces the defining signs of REM sleep: (1) low-voltage

and fast-wave EEG activity and (2) suppression of postural motor tone. Important for the changes in EEG activity is reactivation of the cholinergic cell groups in the pons and basal forebrain that were relatively inactivated during non-REM sleep (see Fig. 85-2). The *spinal* motor activity in REM sleep is suppressed through recruitment of descending neural circuits that involve glycine (principally) and GABA (see Fig. 85-2). However, the periods of major suppression of upper airway muscle activity that are also seen in REM sleep do not seem to involve the same mechanism. The genioglossus muscle activity in REM sleep is suppressed through two additional processes: (1) *disfacilitation* (i.e., withdrawal of excitatory inputs), mediated principally by reduced noradrenaline and serotonin excitation at the hypoglossal motor pool, and (2) *inhibition* mediated by a newly identified muscarinic receptor mechanism linked to G protein-coupled potassium channels.³ The latter is illustrated in Figure 85-2, with the circuitry further explained in “Breathing and Its Control.”

THE “SLEEP SWITCH”

There are *mutually opposing* interactions between the wakefulness-promoting neuronal systems (see Fig. 85-1A) and the non-REM sleep-promoting neuronal systems (see Fig. 85-1B). This organization leads to wakefulness being associated with both a relatively *high level* of activity in the wake-promoting neuronal arousal systems *combined with* a relatively *low level* of activity in the opposing sleep-promoting GABA system (see Fig. 85-1A, panel ii). In contrast, non-REM sleep is associated with both a relatively *high level* of activity in the sleep-promoting GABA system *combined with* a relatively *low level* of activity in the opposing wake-promoting neuronal arousal systems (see Fig. 85-1B, panel ii).

The mutually opposing interactions between the wake-promoting and sleep-promoting neuronal systems produces a situation wherein the brain is in a stable state when *either* one of the respective neuronal systems dominates. This arrangement constitutes the “*sleep switch*”, in which the position of the switch is stable in either state because when one side is active the alternate state is simultaneously inhibited (see Fig. 85-1). In non-REM sleep, for example, the activation of GABA neurons reinforces their own activation via

Figure 85-1 Schema showing the main neuronal groups and their organizational interactions for generating the brain states of wakefulness (A) and non-rapid eye movement (non-REM) sleep (B). Shown (i) are the major neuronal clusters whose ascending projections are responsible for producing the electrocortical arousal of wakefulness and whose descending projections influence brain-stem autonomic networks and spinal motor activity. Non-REM sleep is generated when these wakefulness-generating systems are inhibited by clusters of neuronal groups containing the inhibitory neurotransmitter gamma-aminobutyric acid (GABA). The organizational structure for the maintenance of wakefulness and non-REM sleep, and the switch between the two states, are also shown (ii and iii). Mutual inhibitory interactions between wakefulness and sleep-promoting neuronal groups lead to the “switch” being stable in either position, thus producing consolidated periods of sleep at night and wakefulness during the day. The propensity to transition to a consolidated period of sleep at night (and later a consolidated period of wakefulness in the morning) is linked to the circadian-mediated decrease (then the later increase) in body temperature: the decrease in body temperature activates the GABA sleep-promoting neuronal systems, whereas the increase deactivates them. The non-REM sleep-active GABA neuronal groups include those in the ventrolateral preoptic region of the thalamus, as well as those in the basal forebrain and anterior hypothalamus. The relative position and sizes of neuronal groups are shown for visual clarity and are not meant to represent their strict anatomic positions. Relatively high levels of neuronal activity are represented by *large symbols and solid lines*, whereas relatively low levels of neuronal activity are represented by *small symbols and dashed lines*. Inhibitory neuronal projections from cell groups are indicated by **■**, and excitatory projections by *solid arrowheads*. See text for further details. (Adapted from Horner RL: Emerging principles and neural substrates underlying tonic sleep-state-dependent influences on respiratory motor activity. *Philos Trans R Soc Lond B Biol Sci* 364, 2553–2564, 2009; Horner RL: Central neural control of respiratory neurons and motoneurons during sleep. Waltham, MA, 2013, Academic Press, pp. 517–524; Saper CB, Scammell TE, Lu J: Hypothalamic regulation of sleep and circadian rhythms. *Nature* 437:1257–1263, 2005. © Richard L. Horner, PhD, University of Toronto.)

REM Sleep Generation and Motor Suppression

Figure 85-2 Schema showing the main neuronal groups and their organizational interactions for generating the brain state of REM sleep. There are currently two explanations of REM sleep generation: one involving interactions of cholinergic and aminergic cell clusters (*top left*) and the other involving interactions of glutamatergic and GABAergic cell clusters (*top right*). Although the finer details are discussed in the text, the upshot is that each can explain the cardinal features of REM sleep: (1) ascending cortical activation and (2) descending spinal motor inhibition. The inhibition of spinal motor activity in REM sleep appears different. For the hypoglossal motor pool, for example, which innervates the musculature of the tongue via cranial nerve XII, a cholinergic mechanism mediates the strong motor inhibition of REM sleep. This inhibition counteracts the inspiratory drive to this motor pool that originates from the ventral respiratory group (VRG) via the pre-Bötzinger complex (PBC) and premotoneurons in the lateral reticular formation (the latter two indicated as inspiratory neurons and color coded in *blue*). The dorsal respiratory group (DRG) is also shown for completeness. The hypoglossal motor pool also receives tonic state-dependent drive from the reticular formation (color coded in *gray*). Inhibitory neuronal projections are indicated by ■, and excitatory projections by solid arrowheads. See text for further details. GABA, Gamma-aminobutyric acid. (© Richard L. Horner, PhD, University of Toronto.)

inhibition of the wake-active neuronal systems at the same time.

EFFECTS OF COMMON NEURODEPRESSIVE DRUGS ON BRAIN AROUSAL STATE

The reciprocally opposing wakefulness and sleep-promoting neuronal systems identified in sections, “*Generation of Wakefulness and Sleep*” and “*Sleep Switch*,” essentially alter the brain arousal state via the associated changes in the balance of excitatory and inhibitory neurotransmitters in the critical brain regions identified in [Figure 85-1](#). The

balance of these brain neurochemicals, however, is not only changed across natural states of wakefulness and sleep, but also the balance is changed in *predictable ways* by the ingestion of commonly used neurodepressive drugs. Such drugs include benzodiazepines, imidazopyridines (nonbenzodiazepine sedative hypnotics), barbiturates, ethanol, and some general anesthetics that are either inhalational (e.g., isoflurane) or injectable (e.g., propofol or etomidate). All these agents interact with binding sites on GABA_A receptors that enhance neuronal inhibition at sites where GABA would otherwise be acting.⁴ There are several sites within the endogenous sleep-wake circuitry identified in [Figure](#)

85-1 where such neurodepressive drugs act to depress the brain arousal state and promote sedation and/or loss of consciousness.⁴ Such agents, therefore, effectively “tip the balance” within the endogenous sleep-wake circuitry “toward” sedation and “away” from brain arousal.

The principle of the *sleep switch* can also be used to understand that the depression of brain arousability that is seen in both natural sleep and with neurodepressive drugs is the product of *two* mechanisms. The first is the augmentation of inhibitory GABAergic influences and the second is the concomitant depression of arousal-related stimulatory influences (see Fig. 85-1B, panel ii). There is a dual effect because these inhibitory and excitatory mechanisms cannot operate independently because of their inherent interconnectedness. This principle has further implications for understanding sleep- and drug-induced respiratory depression.

APPLICATION TO SLEEP AND DRUG-INDUCED RESPIRATORY DEPRESSION

The organization of the sleep switch and its application to understanding sleep and drug-induced brain sedation (see “Effects of Common Neurodepressive Drugs on Brain Arousal State”) also has direct applications to understanding respiratory depression. The respiratory network and its associated control systems are themselves influenced by the same state-dependent arousal/sleep systems illustrated in Figures 85-1 and 85-2. Such wakefulness and sleep-dependent neuronal systems also have significant projections to the respiratory network.

Accordingly, during both natural sleep and in the presence of many commonly used sedative and anesthetic drugs, there is both augmentation of the GABAergic inhibitory system and corresponding reductions in excitatory influences from the brain arousal systems (as outlined in “Effects of Common Neurodepressive Drugs on Brain Arousal State”). The net result is a tipping of the balance in the sleep switch toward low brain arousability *plus* alteration of drives to the respiratory network. As further outlined in “Breathing and Its Control,” these state-dependent drives affect the musculature particularly of the upper airways, thus predisposing to obstructive sleep apneas and hypopneas in susceptible individuals.⁵ In essence, the brain functions as a gain-setting device for breathing by altering brain neurochemistry of the key elements of respiratory control: the respiratory neurons, the motoneurons, and the sites involved in the reflex modulation of breathing (see “Breathing and Its Control”).

BREATHING AND ITS CONTROL

The complexity of the brain-stem respiratory network can be distilled to three essential elements:

1. *Respiratory neurons* that generate respiratory rhythm and drive the expression of rhythmic activity in other components of the respiratory network.
2. *Respiratory motor pools* that innervate and activate the primary and secondary muscles of breathing. The primary respiratory muscles are so designated because

they *generate* airflow (e.g., the diaphragm). In contrast, the secondary (accessory) muscles of breathing do not generate airflow but either significantly modulate its passage (e.g., pharyngeal muscles that maintain a patent upper airway) or otherwise support the act of breathing (e.g., the intercostal muscles that contribute to the maintenance of lung volume).

3. *Chemosensors* that detect alterations in blood gases and elicit a physiologic response. In the case of hypoventilation during sleep, for example, the appropriate physiologic response includes *both* an attempted chemoreceptor-mediated increase in ventilation *and* arousal from sleep. The importance of arousal from sleep is critical to survival in some situations when the ventilatory response is futile by itself, for example, shaking off a suffocating blanket in the case of a sleeping infant to prevent asphyxia and risk of sudden infant death syndrome.

The following sections identify the key circuits that generate breathing and control its regulation.

RESPIRATORY NEURONS

Organization

Figure 85-3 illustrates the main components of the respiratory network generating respiratory rhythm and motor activation. The *ventral respiratory group* (VRG) contains Bötzing complex (expiratory) neurons, pre-Bötzing complex (inspiratory) neurons, rostral ventral respiratory group (predominantly inspiratory) neurons, and caudal ventral respiratory group (predominantly expiratory) neurons. The *dorsal respiratory group* (DRG) contains mainly inspiratory neurons. The DRG and its associated regions of the nucleus of the solitary tract are also the projection sites for afferents important to the reflex control of breathing: the carotid and aortic chemoreceptors and baroreceptors, and lung vagal afferents.

The brain stem also includes motoneurons of the hypoglossal and trigeminal motor nuclei that innervate muscles important to the maintenance of upper airway patency (see Fig. 85-3).⁵ Regions of the nucleus ambiguus also contain motoneurons that innervate the muscles of the larynx and pharynx via the vagus, glossopharyngeal, and accessory nerves. Respiratory neurons in the pons (not shown) also modulate the activity of medullary respiratory neurons.

Respiratory Rhythm and Motor Activation

Figure 85-3 also illustrates that some respiratory neurons are identified as *propriobulbar*, that is, neurons that project to, and influence the activity of, other medullary respiratory neurons but themselves do not project to motoneurons.⁵ Others are identified as *bulbospinal respiratory pre-motoneurons*, that is, neurons that project to spinal motoneurons, which in turn innervate the respective respiratory pump and abdominal muscles of breathing.

Inspiration

A particularly important propriobulbar respiratory neuronal group is the pre-Bötzing complex. This region plays a key role in generating the fundamental respiratory rhythm

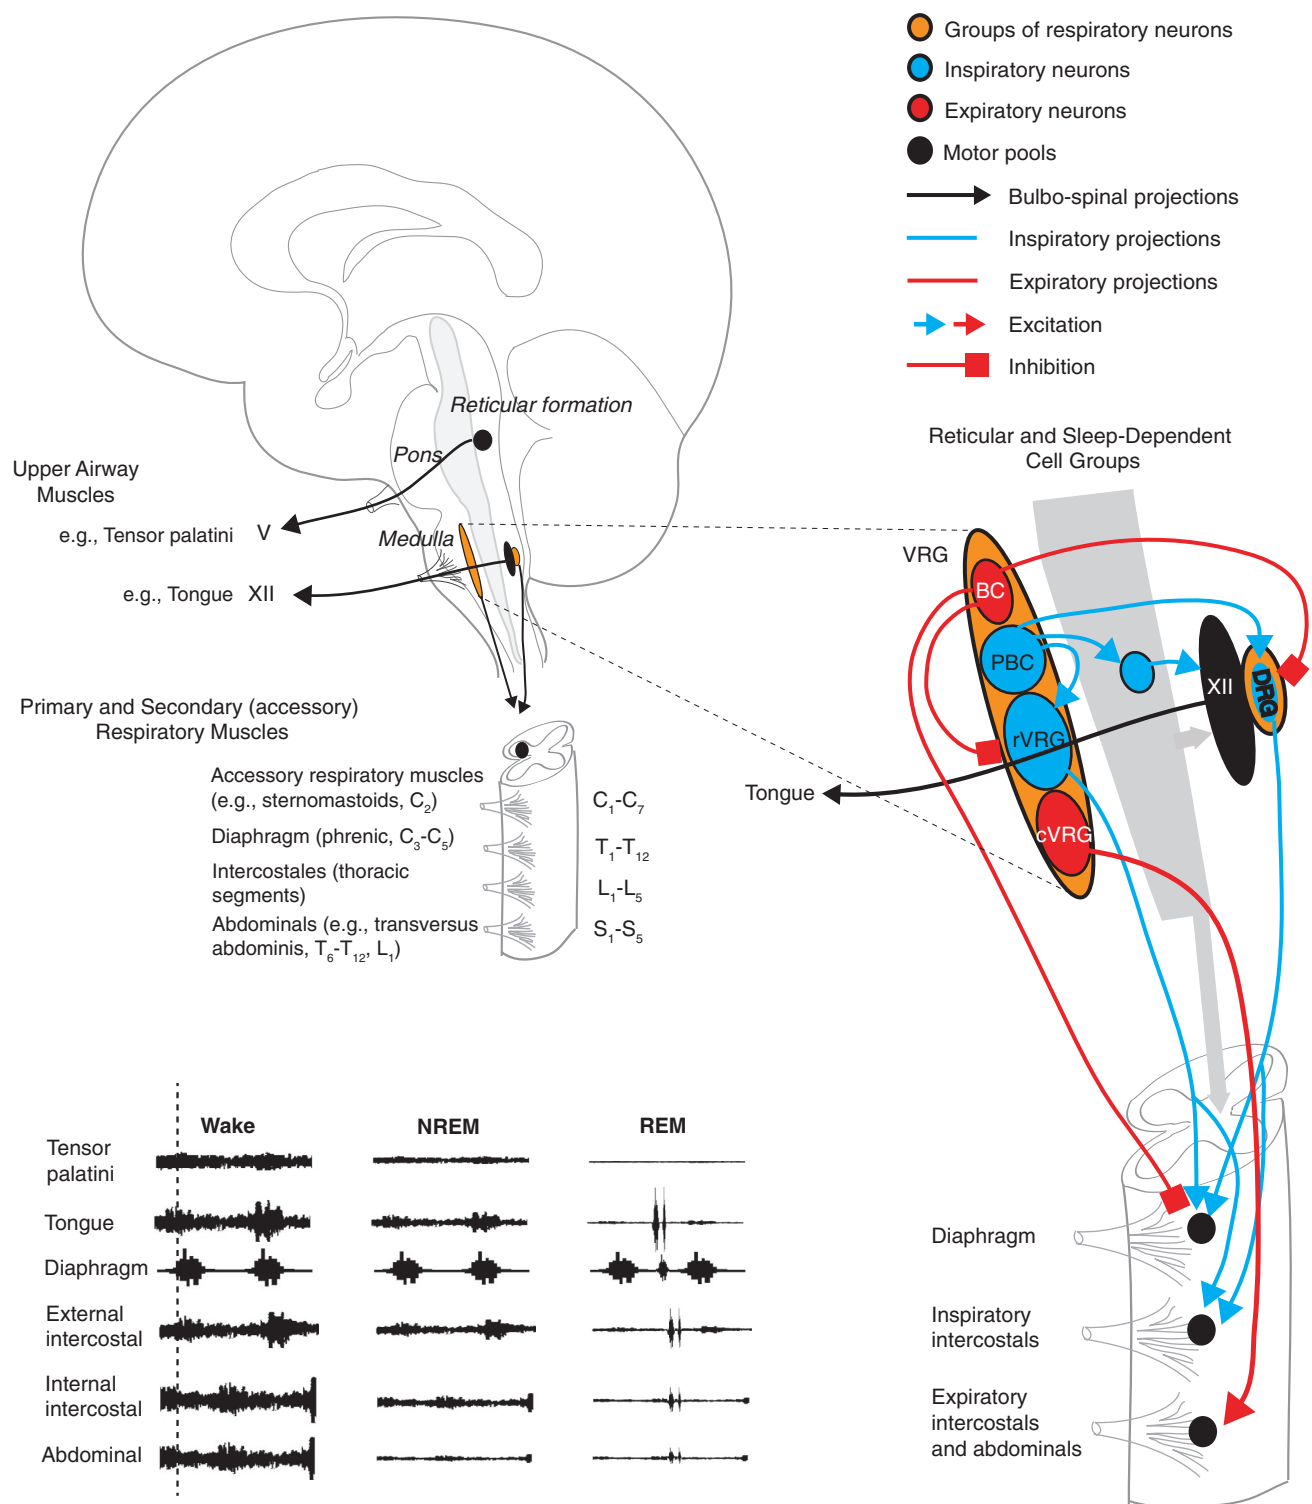

Figure 85-3 Schema showing some of the main neuronal groups and their organizational interactions for the generation of efferent motor output to different respiratory muscles. On the upper left are shown the main neuronal groups and selected motor pools innervating the muscles of the upper airway and the primary and secondary (accessory) muscles of the respiratory pump. On the right, at higher magnification, are shown the main clusters of neurons comprising the ventral and dorsal respiratory groups (VRG and DRG, respectively), and their projections to other neurons comprising the respiratory network. The innervation of the hypoglossal motor pool by state-dependent neurons of the reticular formation is also shown. See text for further details on the relevance of this latter point. At the lower left, the electromyographic activities of various respiratory-related muscles are also shown: palatal, tongue, diaphragm and the accessory, intercostal, and abdominal respiratory muscles. Note that the level of respiratory-related and tonic activities varies for different muscles, with some muscles such as the tensor palatini expressing mainly tonic activity and others, like the tongue and intercostals, expressing both tonic and respiratory activity. This relative balance of tonic and respiratory-related activity can change across sleep-wake states; with tonic activity being typically suppressed in sleep. The onset of muscle activity with respect to the diaphragm is shown by the dashed line. BC, Bötzinger complex; cVRG, caudal VRG; PBC, pre-Bötzinger complex; rVRG, rostral VRG. See text for further details. in mammals.⁶ Pre-Bötzinger complex neurons drive activation of bulbospinal neurons of the DRG and VRG during inspiration, which then activate spinal inspiratory phrenic and intercostal motoneurons (see Fig. 85-3). Inactivation of pre-Bötzinger complex neurons in animal models leads to ataxic breathing and central apneas, especially in sleep.^{7,8} The pre-Bötzinger complex is also a critical site mediating respiratory rate depression by opioids.⁹

Expiration

In expiration, the expiratory neurons of the Böttinger complex inhibit inspiratory pre-motoneurons and motoneurons (see Fig. 85-3). Also, in expiration, the caudal ventral respiratory group neurons increase excitability of spinal expiratory motoneurons (see Fig. 85-3), although this excitation does not necessarily manifest as demonstrable expiratory muscle activation at rest.

Respiratory Rhythm Generation and Central Apneas

The automatic and nonconscious rhythm of breathing is ultimately generated by the intrinsic membrane properties and connections of the individual neurons that comprise the respiratory network. Essential to expression of this rhythmicity, however, is provision of a sufficient level of underlying tonic excitation. Key sources of tonic excitation are from the aforementioned wakefulness-dependent neural systems (see Fig. 85-1) as well as the peripheral and central chemoreceptors (Fig. 85-4).

An important physiologic principle that emerges from identification of the necessity and sufficiency of tonic exci-

tation for respiratory rhythm generation is that removal of such tonic excitation can abolish respiratory rhythm. Sleep or neurodepressive drugs (see Fig. 85-1), or reduced chemoreceptor inputs (see “Breathing Is Dependent on Feedback Regulation in Sleep”), can each lead to cessation of respiratory rhythm and development of central sleep apneas.

RESPIRATORY MOTOR POOLS AND MUSCLE ACTIVITY

Respiratory Muscles Vary in the Degree of Their Relationship to Breathing

Different respiratory muscles express varying degrees of respiratory-related activity and/or tonic (i.e., nonrhythmic, continuous, or background) activation. The diaphragm, for example, is almost exclusively respiratory-related while the palatal, tongue, intercostal, and abdominal muscles express both respiratory and tonic activities, to varying degrees. The physiologic basis for this variation is that the respiratory neurons that ultimately drive the respective respiratory muscles themselves vary in the strength of their relationship to breathing.¹⁰ Some respiratory neurons, for example, are almost exclusively driven by respiratory rhythm-generating neurons and are weakly influenced by other inputs. In contrast, there are some respiratory neurons that are weakly influenced by respiratory rhythm-generating neurons but more strongly influenced by tonic nonrespiratory inputs.¹⁰ Such tonic nonrespiratory inputs can arise from the sleep state-dependent cell groups identified in Figure 85-1.

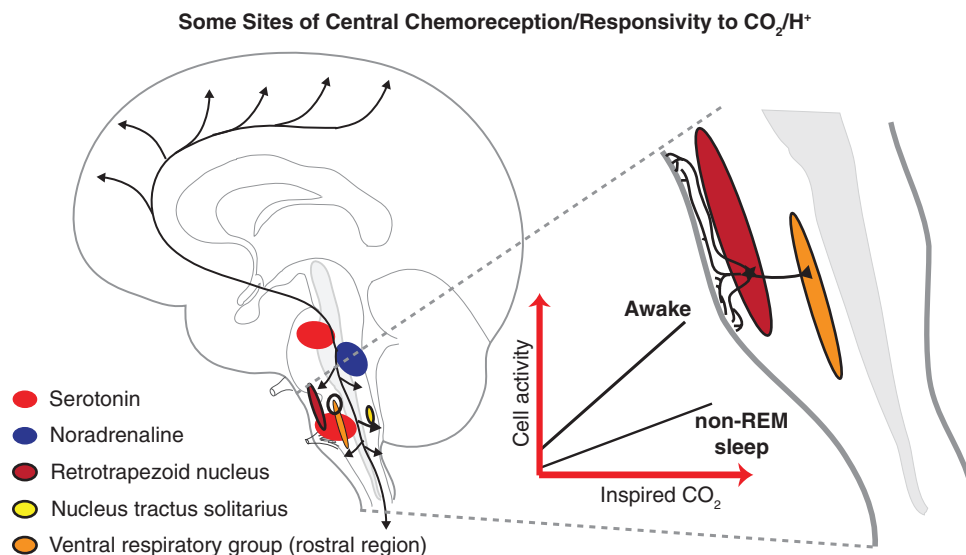

Figure 85-4 Sites of chemoception/responsivity to changes in CO_2/H^+ in the brain. Some of these sites are intimately associated with regulation of brain arousal in sleep and wakefulness (e.g., serotonin and noradrenaline containing cell clusters; see Fig. 85-1). Other sites are intimately associated with respiratory neuronal activity and reflex responses (e.g., nucleus tractus solitarius and ventral respiratory group; see Fig. 85-3). A key site that is intrinsically sensitive to alterations in CO_2/H^+ is the retrotrapezoid nucleus located near the ventral surface of the medulla. This region of the brain is magnified in the panel on the right. Branching dendrites from retrotrapezoid neurons “taste” the cerebrospinal fluid at the medullary surface and are activated by increased CO_2 (lowered H^+). Activity related to CO_2/H^+ influences several brain regions, including the ventral respiratory group, so driving breathing. The inset shows the response of a brain-stem serotonergic neuron to increases in inspired CO_2 . There are several features of note: (1) baseline activity (i.e., at zero inspired CO_2) is higher in wakefulness than in sleep, in keeping with Figure 85-1; (2) the neuronal activity at any given inspired CO_2 is greater in wakefulness than in sleep; (3) the slope (gain) of response is also greater in wakefulness than in sleep. Together, these three features parallel the overall respiratory responses to CO_2 as measured by changes in ventilation (compare with Fig. 85-7). © Richard L. Horner, PhD, University of Toronto.)

Effects of Sleep

The identification of respiratory neurons and motoneurons that vary in the strength of their relationship to breathing assumes greater significance because of the physiologic principle identified by John Orem from Texas Tech University.¹⁰ Those respiratory neurons that are most strongly driven by respiratory rhythm-generating neurons are *least* affected by the transition from wakefulness to non-REM sleep. In contrast, those respiratory neurons that are more strongly influenced by tonic nonrespiratory inputs are *most* affected by the change from wakefulness to sleep. In the latter case, activity within certain respiratory muscles can cease or be markedly depressed during sleep, especially those showing prominent tonic muscle activity in wakefulness, such as the muscles of the upper airway and chest wall (see Fig. 85-3). The key physiologic and clinical implications of this effect are identified in “Upper Airway Motor Tone and Compensatory Reflex Responses are Particularly Sensitive to Depression In Sleep”; the loss of the tonic input to muscles of the upper airway is one of the major reasons for the suppression of upper airway muscle activity in sleep and the susceptibility to obstructive sleep apneas.

CHEMOSENSORS AND CHEMOREFLEXES

Location and State-Dependence of Responses

Arterial O_2 and CO_2 levels are regulated by peripheral chemoreceptors located at the bifurcation of the common carotid arteries, and central chemoreceptors located in the brain. More specifically, the central chemoreceptors are located close to the ventral surface of the medulla in the caudal region of the retrotrapezoid nucleus (see Fig. 85-4).¹¹ Cells in this region of the retrotrapezoid nucleus are intrinsically sensitive to changes in CO_2/H^+ . These CO_2/H^+ sensitive neurons have dendrites that extend to the ventral medullary surface by which they sense the pH of the surrounding cerebrospinal fluid. They also have axons that project to the rostral region of the VRG by which they drive respiratory network activity.

In addition to the retrotrapezoid nucleus, some of the wakefulness-active/sleep-inactive cell groups identified in Figure 85-1, such as serotonergic and noradrenergic neurons, are also responsive to alterations in CO_2/H^+ levels (see Fig. 85-4). For any given inspired CO_2 , the activity and responsivity (i.e., slope of response) of such neurons is reduced in sleep compared to wakefulness. As identified in later sections, this change in cell activity in response to hypercapnia from wakefulness to sleep parallels the change in overall ventilatory response.

INTEGRATIVE PHYSIOLOGIC MECHANISMS UNDERPINNING RESPIRATORY DYSFUNCTION AND INSTABILITY DURING SLEEP

The aim of this section is to integrate the key concepts and principles identified in the preceding sections in order to

identify the variety of mechanisms that can predispose to respiratory dysfunction in sleep.

BREATHING IS DEPENDENT ON FEEDBACK REGULATION IN SLEEP

Principle

A prevailing level of tonic excitation into the respiratory network is essential to drive respiratory rhythm and muscle activation (see “Respiratory Rhythm Generation and Central Apneas”). The brain arousal systems of wakefulness (see Fig. 85-1) provide a major source of such excitation to modulate breathing volitionally and/or non-volitionally, together termed *behavioral* influences or the “wakefulness stimulus” to breathing.¹² Figure 85-5 illustrates that such behavioral influences on respiratory network activity are reduced or withdrawn as one moves from wakefulness to non-REM sleep. As a result, the respiratory system becomes *dependent* upon feedback regulation in non-REM sleep to sustain sufficient activity.

Tonic activity of the peripheral and central chemoreceptors is *normally* sufficient to sustain effective breathing in non-REM sleep. The key consequence of the organization identified in Figure 85-5, however, is that *any* reduction or defect in feedback chemoreceptor control, for *any* reason, causes severe respiratory disturbance in non-REM sleep, a time when the stimulatory effects of wakefulness on the respiratory system are withdrawn. Interestingly, compared with the situation in non-REM sleep, in REM sleep, the heightened state of brain arousal (see Fig. 85-3) can restore sufficient nonspecific behavioral drives to the respiratory network to restore breathing.

Application

Hypocapnia is a potential cause of central apnea. Interestingly, hypocapnia, by itself, is not sufficient to elicit central

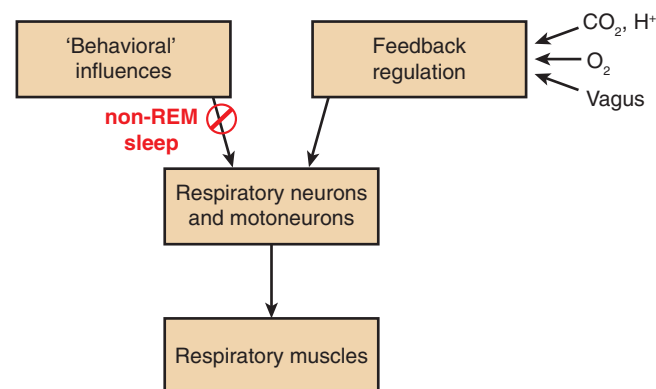

Figure 85-5 Conceptual model showing that efferent output from respiratory neurons and motoneurons is controlled by behavioral influences and feedback regulation. Feedback regulation includes control by CO_2/H^+ , O_2 levels, and responses to mechanical and ventilatory events in the airways and lung via the vagus nerves. Notably, behavioral influences are significantly reduced or withdrawn in non-REM sleep. The physiologic principle that arises from this effect is that breathing is essentially *dependent* on metabolic (CO_2 and O_2) control in non-REM sleep. The consequence is that *any* defect in metabolic control, for *any* reason, causes severe respiratory disturbance in sleep, but not necessarily in wakefulness. Behavioral influences include both volitional and nonvolitional (but wakefulness-dependent) mechanisms that influence breathing. (© Richard L. Horner, PhD, University of Toronto.)

apneas in wakefulness or in REM sleep because of the concomitant presence of behavioral influences on breathing. However, in non-REM sleep, hypocapnia can elicit central apneas because the stimulatory effects of brain arousal (i.e., behavioral influences) to the respiratory network are absent. This critical combination of factors, that is, hypocapnia and absence of behavioral influences to breathing in non-REM sleep, removes two of the crucial sources of tonic drives to the brain-stem network that normally generate and sustain breathing. Hypocapnia may be present at the onset of sleep as a result of chronic hyperventilation in wakefulness caused, for example, by heightened chemoreceptor drive (e.g., resulting from congestive heart failure) or by exaggerated behavioral influences on breathing (e.g., caused by anxiety). Hypocapnia at sleep onset can also result from the transient hyperventilation caused by sleep disturbance and brief arousal from sleep: the hyperventilation predisposing to unstable breathing by depleting the CO_2 reserve (defined in “Loop Gain and its Importance”). In these settings of hypocapnia, central apneas may become clinically important in non-REM sleep.

As a second example of the importance of tonic stimulation, patients with *congenital central hypoventilation syndrome* (CCHS) who have a defect in chemoreception exhibit major disturbances of ventilation in non-REM sleep but ventilate normally during wakefulness and during REM sleep. In more than 99% of CCHS patients, mutations have been found in the *paired-like homeobox 2b* (*PHOX2B*) gene, a gene expressed by neurons involved in peripheral and central chemoreception. The fact that *PHOX2B* is not expressed by respiratory neurons can perhaps explain the ability of these patients to breathe in wakefulness, because the mutation does not affect respiratory neurons. Rather, the state of wakefulness itself provides sufficient excitatory drive to the respiratory system to mask the major defect in chemoreceptor activity caused by the *PHOX2B* mutation. The ability of the CCHS patients to breathe normally in REM sleep further reinforces the principle that the relatively high levels of brain activation inherent to REM sleep (see Fig. 85-2) can provide sufficient restoration of behavioral drives to the respiratory network to reinstitute breathing.

As a final example that highlights the powerful effect of wakefulness as an independent driver of respiratory activity, it is noted that deep non-REM sleep and anesthesia are the most vulnerable states for respiratory rate depression by opioids at the pre-Bötzinger complex.⁹ In this situation breathing can be sustained by wakefulness even when opioids are present at the pre-Bötzinger complex, a key site for respiratory rhythm generation in mammals. However, loss of this important wakefulness stimulus to breathing can lead to hazardous respiratory depression in non-REM sleep and anesthesia. This example further emphasizes the principle that wakefulness per se can provide sufficient excitatory drive to the respiratory system to mask (at least partially) otherwise significant defects in respiratory control, in this case defects induced by drugs. The clinical relevance of this principle is that sedating agents can be deemed well tolerated in the initially alert patient but, when the stimulating effects of wakefulness are withdrawn during sleep, the patient may suffer significant respiratory depression (i.e., “crash”). Such a scenario is particularly dangerous when patients with sleep-related breathing problems

use opioids for pain management, especially if taken in combination with benzodiazepines and/or alcohol at home.

LOOP GAIN AND ITS IMPORTANCE

Principle

Loop gain is an engineering term that describes the overall gain, or sensitivity, of a feedback control system. A high gain system responds quickly and vigorously to any given perturbation; a low gain system responds slowly and weakly. The factors contributing to overall loop gain are *plant gain* and *controller gain* (Fig. 85-6). Plant gain largely reflects the effectiveness of breathing to eliminate CO_2 , that is, how much a given change in ventilation itself affects arterial CO_2 . Controller gain largely reflects chemoresponsiveness, for example, how much a given change in arterial CO_2 itself affects ventilation.

Overall, a high loop gain promotes ventilatory instability because it predisposes to a situation whereby a small perturbation in ventilation can trigger cessation of breathing because the change of the arterial PCO_2 makes it more likely to reach the *apnea threshold* (see Fig. 85-6). Loop gain is defined and quantified as the magnitude of the response to a given disturbance in breathing (e.g., hyperpnea) divided by the magnitude of the causal disturbance itself (e.g., an apnea, a sigh). If loop gain is less than 1, then the system corrects itself (i.e., breathing normalizes), but if loop gain is 1 or greater, then the system remains unstable. In the latter case, a large ventilatory response to a particular perturbation in breathing can itself become a subsequent disturbance, and so precipitate persistent instability. Overall, an increase in plant and/or controller gains can destabilize breathing because they lower the effective CO_2 reserve, that is, the amount by which an increase in ventilation lowers arterial PCO_2 to the chemical apnea threshold¹³ (see Fig. 85-6).

Application

There are several situations whereby altered plant and/or controller gains can predispose to sleep-disordered breathing. For example, when there is low functional residual capacity, dead space, or metabolic CO_2 production, a given increase in ventilation more effectively lowers arterial PCO_2 toward the apnea threshold. This is because in each situation there is an increase in plant gain and a corresponding increased tendency to unstable breathing by virtue of the effectively reduced CO_2 reserve¹³ (see Fig. 85-6C). Interventions such as nasal continuous positive airway pressure or positive end-expiratory pressure can help stabilize breathing in this context by increasing both functional residual capacity and dead space, thereby effectively reducing plant gain. Subtler distinctions between steady state and dynamic plant gains are discussed elsewhere.¹⁴ Similarly, patients with alveolar hypoventilation secondary to central nervous system disturbances or neuromuscular weakness are also predisposed to unstable breathing in sleep. This predisposition is also explained by virtue of their lowered CO_2 reserve, despite having an elevated resting arterial PCO_2 , due to a shift to the right in their equilibrium position for resting breathing¹³ (see orange symbol on Fig. 85-6C). Patients with heart failure also experience unstable breathing during

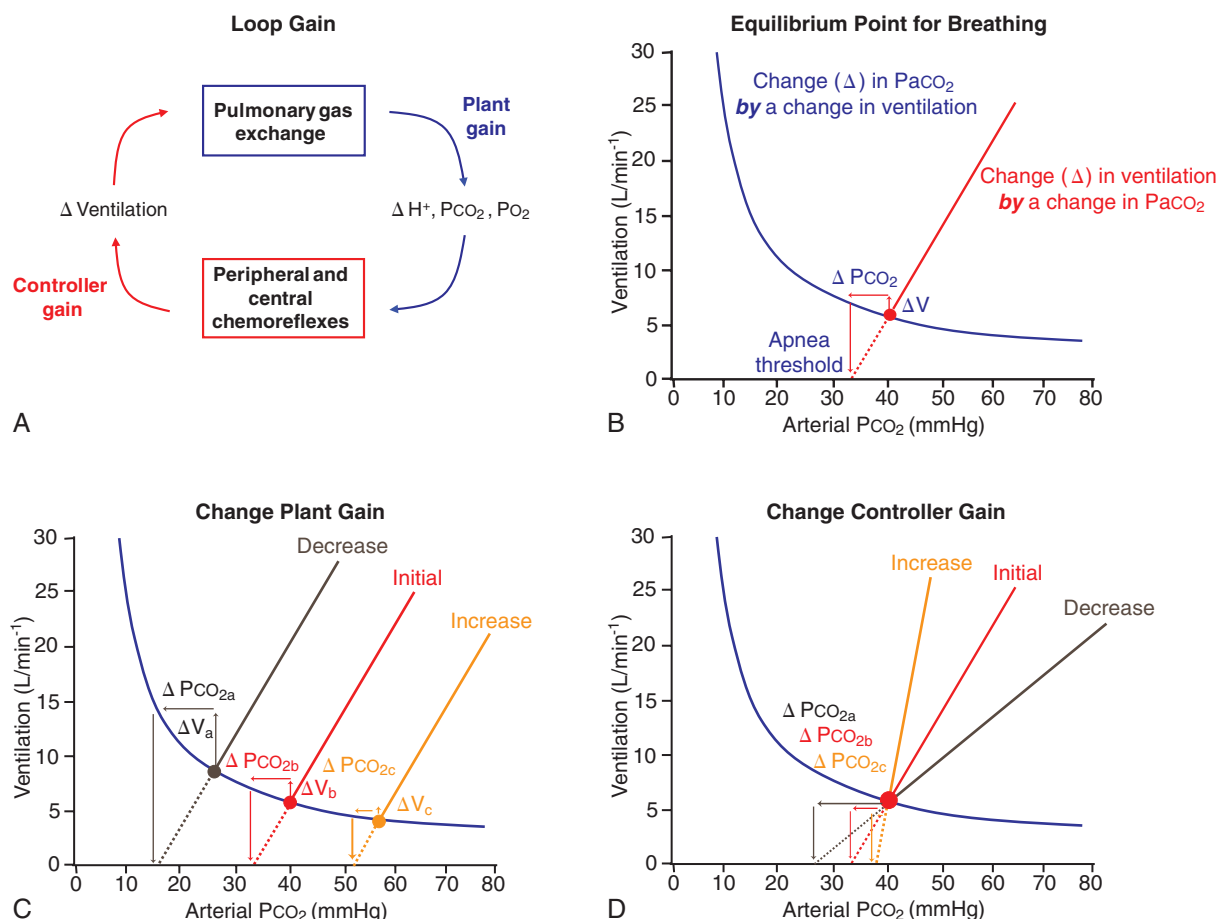

Figure 85-6 Schema to illustrate how loop gain (comprised of plant and controller gains) determines the equilibrium point for breathing and influences breathing stability/instability. **A**, Pulmonary gas exchange changes ventilatory variables, which themselves influence breathing. *Plant gain* largely reflects the effectiveness of ventilation to eliminate CO_2 (e.g., with a low functional residual capacity, low dead space, or low metabolic rate). *Controller gain* is largely a result of chemoresponsiveness (e.g., increased in heart failure). **B**, The equilibrium point for stable breathing is illustrated by the red symbol (●). This equilibrium point for resting breathing sits at the intersection of the ventilatory response to increased arterial PCO_2 (red line) and the change in arterial PCO_2 that results from a change in ventilation (the metabolic hyperbola, blue line). Reductions in arterial PCO_2 reduce ventilation according to the ventilatory response (dashed red line), until apnea is seen (the *apnea threshold*). The magnitude of the increase in ventilation that lowers arterial CO_2 to the apnea threshold is termed the CO_2 reserve. **C** and **D**, The predisposition to unstable breathing based upon the equilibrium position for resting breathing and the apnea threshold. Decreases in plant or controller gains produce a situation in which a larger increase in ventilatory disturbance is necessary to deplete the CO_2 reserve before apnea (**C** and **D**, brown line). In contrast, increases in plant or controller gains produce a situation in which a smaller increase in ventilatory disturbance is necessary to deplete the CO_2 reserve before apnea (**C** and **D**, orange line). The physiologic principle that arises from this effect is that the predisposition to ventilatory instability and disordered breathing in sleep is significantly determined by the plant and controller gains. For example, patients with alveolar hypoventilation secondary to central nervous system disturbance or neuromuscular weakness are predisposed to periodic breathing in sleep despite having an elevated resting arterial CO_2 (point ● in **C**). Likewise, patients with heart failure who have sympathetic nervous system-mediated increases in chemoreflex responsiveness are also predisposed to periodic breathing in sleep (point ● in **D**). (Adapted from Philipson EA, Bowes G: Control of breathing during sleep. In Cherniack NS, Widdicombe JG, editors: *Handbook of physiology*, section 3, control of breathing, part 2, the respiratory system, vol. II, Bethesda, MD, 1986, American Physiological Society, pp. 649–689; Dempsey JA, Veasey SC, Morgan BJ, O'Donnell CP: Pathophysiology of sleep apnea. *Physiol Rev* 90:47–112, 2010. © Richard L. Horner, PhD, University of Toronto.)

sleep. In these patients, the increased chemoresponsiveness associated with heart failure-induced sympathetic nervous system activation leads to increased controller gain and again a diminished CO_2 reserve (see Fig. 85-6D).

AROUSAL FROM SLEEP: A CONSEQUENCE AND CAUSE OF RESPIRATORY DISTURBANCE

Principle

The ventilatory responses to hypoxia and hypercapnia are fundamental to the homeostatic regulation of arterial blood gases. These ventilatory responses are reduced in non-REM

sleep compared to wakefulness, and are further reduced in REM sleep¹⁵ (Fig. 85-7). The threshold level of hypercapnia to provoke arousal from sleep is similar, on average, between non-REM and REM sleep in humans, whereas the level of asphyxial hypoxia (e.g., hypoxia of the type experienced in obstructive sleep apnea) often elicits arousal at lower arterial oxygen saturations in REM sleep than non-REM sleep¹⁵ (see Fig. 85-7). Isocapnic hypoxia, however, is generally a weak stimulus to elicit arousal from sleep and the threshold is similar, on average, between non-REM and REM sleep.¹⁵

The normal decrease in ventilation from wakefulness to sleep usually results in trivial changes in arterial O_2 saturation because the starting arterial PO_2 is on the flat portion

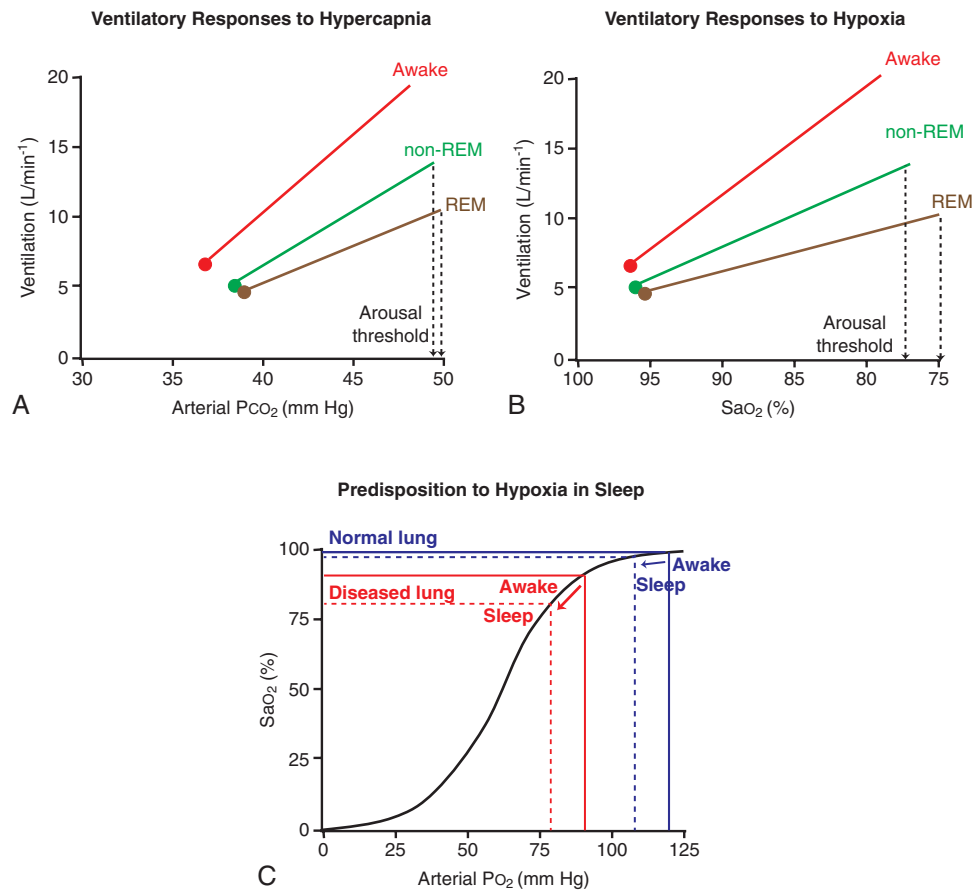

Figure 85-7 Summary graphs showing the ventilatory and arousal responses to hypercapnia (A) and hypoxia (B). Note: (1) The decrease in basal ventilation from wakefulness (●) to non-REM (●) and REM (●) sleep; (2) ventilation is greater in wakefulness at any given elevated arterial CO₂ or lowered arterial oxygen saturation (SaO₂) compared to non-REM sleep and REM sleep; (3) the slope (gain) of the ventilatory responses to hypercapnia and hypoxia is also greater in wakefulness than in non-REM sleep and is most depressed in REM sleep. Also shown are the thresholds for hypercapnia (A) and asphyxial hypoxia (B) to elicit arousal from sleep (see text for additional details). The figure also illustrates the relationship between the starting (waking) arterial partial pressure of O₂ and the magnitude of the decrease in SaO₂ from wakefulness to sleep (C). Normal decreases in ventilation from wakefulness to sleep lead to normal decreases in arterial PO₂ but only modest or trivial decrease in SaO₂ in sleep, because the starting arterial PO₂ is on the flat portion of the oxyhemoglobin dissociation curve (blue lines, C). Such a situation, for example, typically would be experienced by individuals living at sea level, or in individuals with healthy lungs and/or with normal ventilation and lung perfusion. The same magnitude of decrease in ventilation and arterial PO₂ from wakefulness to sleep, however, can lead to a large decrease in SaO₂ if an individual is initially hypoxic and therefore initially positioned on the steep portion of the dissociation curve (starting SaO₂ of about 90%). For clinical relevance see text. (Adapted from Douglas NJ: Respiratory physiology: understanding the control of ventilation. In Kryger MH, Roth T, Dement WC, editors: *Principles and practice of sleep medicine*. St. Louis, 2011, Elsevier, Saunders, pp. 250–258; Thompson SR, Ackermann U, Horner RL: Sleep as a teaching tool for integrating respiratory physiology and motor control. *Adv Physiol Educ* 25:101–116, 2001; Horner RL: Pathophysiology of obstructive sleep apnea. *J Cardiopulmon Rehabil Prev* 28:289–298, 2008; Horner RL: Respiratory physiology. In Kushida C, editor: *Encyclopedia of sleep*, vol. 1. Waltham, MA, 2013, Academic Press, pp. 517–524. © Richard L. Horner, PhD, University of Toronto.)

of the oxyhemoglobin dissociation curve. However, there can be a larger decrease in arterial O₂ saturation from wakefulness to sleep if an individual is *initially* hypoxemic and therefore initially positioned on the steep portion of the dissociation curve (see Fig. 85-7). This situation can be seen with an individual at altitude, with lung disease, or with depressed ventilation and/or impairments in breathing for *any* reason. The physiologic principle that arises from these relationships is that *any* situation that lowers arterial PO₂ in wakefulness for *any* reason (e.g. altitude, lung disease) predisposes to worsening hypoxemia in sleep, *especially* in REM sleep.

Application

Interactions between the ventilatory responses to hypercapnia and hypoxia, and arousal from sleep, can provoke unstable breathing and central apneas. Figure 85-8 outlines

these interactions using the ventilatory responses to hypercapnia as the example (see legend for additional details specific to Fig. 85-8). As a general rule, however, the same predisposition to unstable breathing during arousal from sleep also applies to the ventilatory responses to hypoxia or to combined hypercapnia and hypoxia (i.e., asphyxia as seen in sleep-disordered breathing). The physiologic principle that arises from these interactions is that *any* separation of equilibrium points for stable breathing in wakefulness and non-REM sleep for *any* reason can lead to unstable breathing and central apneas at sleep onset, especially when sleep onset follows a perturbation to breathing such as arousal from sleep (see Fig. 85-8). Such a separation could be seen in one or more clinically relevant scenarios. For example, the equilibrium point for waking ventilation could shift to the left in situations of acute or chronic hyper-ventilation caused by anxiety, congestive heart failure, or

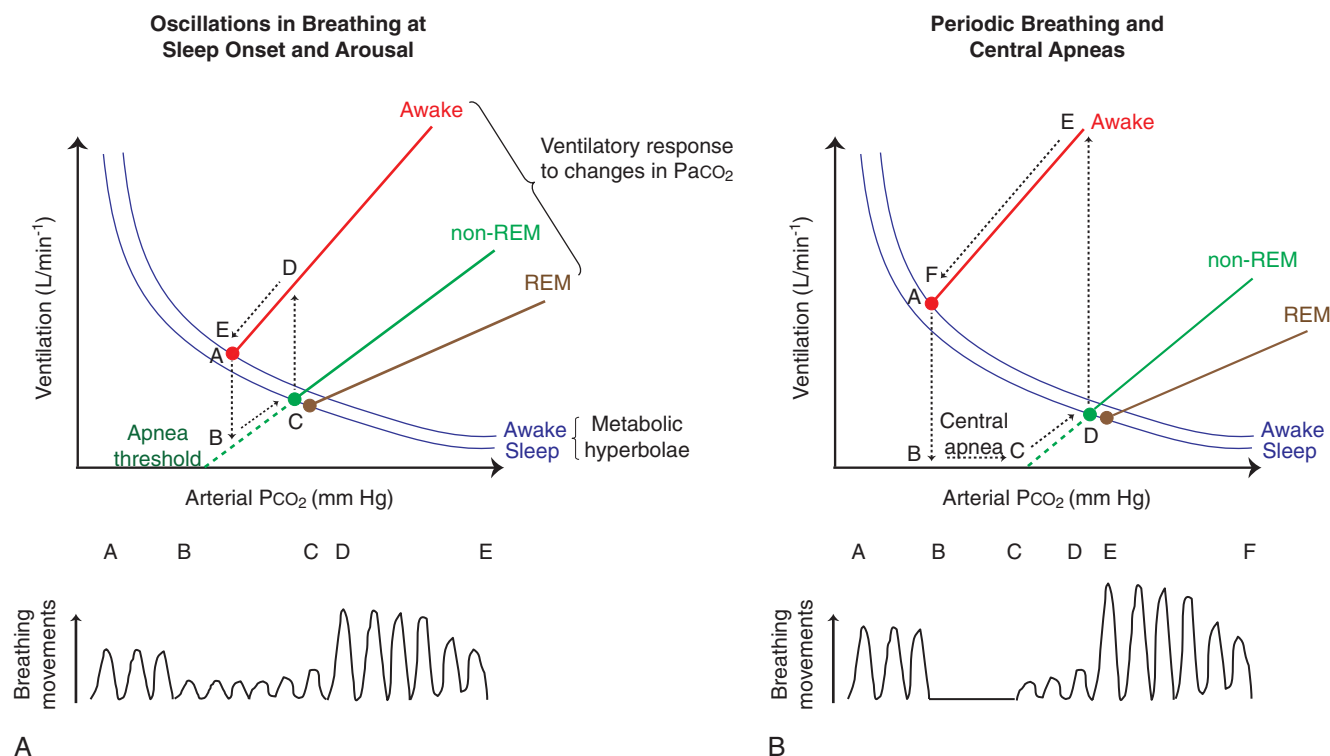

Figure 85-8 Schema to illustrate how interactions between the ventilatory responses to hypercapnia and transitions between sleep and wakefulness can provoke unstable breathing and central apneas. The equilibrium point for stable breathing in wakefulness is illustrated by point A (●) in the left graph. This equilibrium point intersects the ventilatory response to increased arterial PCO_2 (red line) and the change in arterial PCO_2 that results from a change in ventilation (the metabolic hyperbola, blue line). The ventilatory response to increased arterial PCO_2 in non-REM and REM sleep are also shown (green and brown lines, respectively). Also shown is how a decrease in arterial PCO_2 in non-REM sleep can result in reduced ventilation and eventually apnea (dashed green line). At sleep onset, the arterial PCO_2 that was previously present in wakefulness (point A) produces lesser ventilation in sleep according to the extrapolation of the ventilatory response to CO_2 in sleep (dashed green line, point B). This decrease in ventilation is out of proportion to metabolic rate so ventilation progressively increases toward the new sleeping equilibrium position (point C, ●). If the patient arouses from sleep, then the arterial PCO_2 that represents the equilibrium point for breathing in sleep (●) now represents a hypercapnic stimulus according to the ventilatory response to CO_2 in wakefulness, such that ventilation increases dramatically (points C to D). The elevated level of ventilation at point D is out of proportion to the prevailing metabolic rate so ventilation progressively decreases toward the waking equilibrium position (points D to E, ●). The cycle of waxing and waning of ventilation with the waxing and waning of wakefulness and sleep continues until sleep is established. The physiologic principle that arises from this effect is that any separation of equilibrium points in wakefulness and non-REM sleep (● and ●), for any reason can lead to periodic breathing and central apneas at sleep onset. Such periodicity and central apnea is shown in the right graph. (© Richard L. Horner, PhD, University of Toronto.)

other causes. Likewise, the equilibrium point for sleeping ventilation could shift to the right with drug-induced respiratory depression. In either case, it is the arousal from sleep per se that acts as the initial perturbation to elicit the unstable breathing and central apnea.

UPPER AIRWAY MOTOR TONE AND COMPENSATORY REFLEX RESPONSES ARE PARTICULARLY SENSITIVE TO DEPRESSION IN SLEEP

Principle

The key source of respiratory drive to the hypoglossal motor pool is *different* than for spinal respiratory neurons; being from the reticular formation for the former and from bulbo-spinal respiratory neurons for the latter (see Figs. 85-2 and 85-3). As a consequence of this and other organizational features, hypoglossal motoneurons are not inhibited in expiration unlike spinal inspiratory motoneurons (see Fig. 85-3). This point identifies that the activity of the genioglossus muscle in expiration is simply a manifestation of the

prevailing tonic inputs. The key physiologic and clinical implications of this organizational principle are explained in the following subsection: “Application”. For now, however, it is important to reiterate that the reticular formation contains cell groups with sleep state-dependent activity (see “Wakefulness and Sleep” and Figs. 85-1 and 85-2). This organizational feature imparts a significant modulation of excitability of the hypoglossal motor pool across natural sleep-wake states, as well as a particular susceptibility to the suppressant effects of neurodepressive drugs (see Fig. 85-1).

Although the reticular formation exerts major effects on the excitability of the upper airway motor pools, it influences the spinal motor pools via the reticulospinal tract (see Fig. 85-3). Notably, this reticular influence on the phrenic motor pool is significantly reduced compared to the upper airway motor pools, because of the reduced density/impact of those reticulospinal connections. The key physiologic and clinical implications of this organizational feature are that the upper airway muscles are more susceptible to changes in activity across the sleep-wake state and with neurodepressive drugs than is the diaphragm. This notion

explains the principle that activity of the diaphragm is relatively preserved across sleep-wake states compared to other respiratory muscles, especially those that serve dual respiratory and nonrespiratory or postural functions such as the muscles of the tongue and chest wall.

Application

There are several implications arising from the differential effects of sleep on the respiratory and tonic components of respiratory muscle activity, particularly for the upper airway muscles (see Fig. 85-3). For example, the tonic activity of the tongue and palatal musculature contributes to both baseline airway size and stiffness, and the decreased activity in sleep is linked to airway narrowing and the pathogenesis of obstructive sleep apnea. Suppression of chest wall muscle activity in sleep is thought to increase the compliance of the chest wall and contribute to a decreased functional residual capacity; these effects can contribute to hypoventilation especially in infants because of the already highly compliant chest wall.

OVERARCHING PRINCIPLE: VARIOUS TRAJECTORIES CAN LEAD TO A SLEEP-DISORDERED PHENOTYPE

As outlined in the previous sections, different individuals can “find their way” to respiratory dysfunction in sleep for varying reasons; that is, different combinations of factors contribute to both pathogenesis and severity in varying degrees. Given that the involvement of these factors in the pathogenesis of respiratory dysfunction in sleep can also vary within and between subjects—including across the night, between sleep states, and at different ages and body weights, and with prescription and nonprescription drugs—there is not one critical mechanism for pathogenesis and not one critical target for therapy for all types of sleep-disordered breathing. The clinical challenge is to devise simple and effective ways to identify the physiologic phenotype of each patient and target the relevant mechanisms operating in each individual. In short, various trajectories can lead to a sleep-disordered phenotype and the specific mechanisms mediating the trajectories need to be identified for each patient to individualize therapy.

CLINICALLY RELEVANT CONCEPTS IN RESPIRATORY CONTROL IDENTIFIED AS “PERTURBATIONS”

OBSESITY

The high and increasing prevalence of obesity has led to an increasing appreciation of its important effects on respiratory function. Whereas the obesity-related syndromes of obstructive sleep apnea and obesity hypoventilation are fairly well defined, obesity also impacts other conditions such as asthma and chronic obstructive pulmonary disease.

Principle

The respiratory effects of obesity can be broadly classified into mechanical influences on the upper airway and chest

wall, neurohumoral effects of various adipocytokines, and the possible effects on central respiratory drive as described by the arterial PCO_2 set point. By its mechanical effects, obesity has an impact on the upper airway via fat accumulation around the air space that increases the propensity for airway collapse.¹⁶ The transmural pressure across the pharyngeal airway is an important variable determining its patency; fat deposition leads to a more negative (less positive) transmural pressure, favoring its collapse. Abdominal fat deposition can further worsen pharyngeal patency by causing small end-expiratory lung volumes that reduce upper airway dimensions by decreasing traction forces. Lowered lung volumes also increase the plant gain and thereby increase the tendency toward unstable breathing in response to a given perturbation (see “[Loop Gain and Its Importance](#)”). By its generation of proinflammatory cytokines, obesity has also been implicated in airway inflammation, perhaps contributing to the development of asthma in obese people. Mouse models have suggested an important role for leptin in the control of breathing; ob/ob leptin-deficient mice hypoventilate and leptin repletion restores their ventilation. However, the impact of leptin on ventilation in humans with obesity is less clear.¹⁷ Finally, by altering arterial PCO_2 set points, obesity may affect central respiratory drive. Some morbidly obese individuals have elevated arterial PCO_2 set points, likely as a result of cumulative CO_2 retention, initially during sleep. It is thought that the elimination of CO_2 following arousal is insufficient to eliminate the CO_2 that has accumulated during antecedent sleep; the result is a gradual elevation of arterial PCO_2 during sleep that eventually persists into wakefulness. However, the underlying genetic and/or neurobiologic mechanisms of obesity hypoventilation syndrome remain to be established.

Application

Obesity is the major reversible risk factor for obstructive sleep apnea. Substantial data show the importance of weight loss in reducing apneas and the magnitude of associated arterial oxygen desaturations. However, several points about this relationship between obesity and obstructive sleep apnea deserve further emphasis. First, weight loss is difficult to achieve through diet and exercise, and thus bariatric surgery is being used increasingly in the management of obstructive sleep apnea. Second, even with substantial weight loss, the improvement in obstructive sleep apnea severity is often modest. For example, weight loss of 10.7 ± 0.7 kg led to a reduction in the apnea-hypopnea index of only 9.7 ± 2 events per hour of sleep.¹⁸ Thus, considerable weight loss may be required to resolve apnea for many patients. Third, several studies have shown that, following either medical or surgical weight loss, obstructive sleep apnea can redevelop over time even without regain of weight. Presumably redistribution of fat and aging both contribute to the recurrence of sleep apnea in these patients. Fourth, some data as well as clinical experience suggest that treatment of sleep apnea is often associated with weight gain.¹⁹ The mechanisms underlying this observation have been debated, but are likely related to the fact that treatment of obstructive sleep apnea reduces energy expenditure during sleep and restores social behaviors associated with calorie intake, such as going out for dinner. Regardless of

the underlying mechanism, diet and exercise instructions should be provided to the majority of obstructive sleep apnea patients regardless of the treatment approach.

HEART FAILURE

Accumulating literature has suggested a *bidirectional* relationship between sleep disturbance and heart disease.²⁰ Sleep deprivation and sleep apnea have both been associated with an increased incidence of cardiovascular disease. In addition, patients with cardiovascular disease have a very high prevalence of sleep-disordered breathing. For example, roughly two thirds of patients with impaired left ventricular systolic function have either central or obstructive sleep apnea. Obstructive and central apneas exist on a spectrum; they often manifest in the same patient and may have similar underlying mechanisms. While some physiologic literature exists regarding the mechanisms underlying unstable breathing in congestive heart failure, the underlying neurobiology is less well defined. However, definitive therapeutic data are lacking, making these associations intriguing but they currently fall short of improving patient care.

Principle

Multiple mechanisms underlie disordered breathing in patients with heart disease. First, chemoreceptor activity is high in patients with congestive heart failure and central sleep apnea (Cheyne Stokes breathing) compared to matched heart failure patients without central apnea.²¹ Thus, controller gain, a major component of overall loop gain (see “[Loop Gain and Its Importance](#)”), is likely high in congestive heart failure patients with central sleep apnea. In patients with pulmonary edema, hypoxemia is commonly present, which may further increase ventilatory drive. Second, because baseline arterial PCO₂ is often low in patients with congestive heart failure, these patients are closer to their apnea threshold than are patients with more stable breathing patterns (see “[Breathing Is Dependent on Feedback Regulation in Sleep](#)” and “[Arousal from Sleep: A Consequence and Cause of Respiratory Disturbance](#)”).²² Third, elevated left atrial pressure per se can increase ventilatory drive and the propensity for apnea by reducing the CO₂ reserve.²³ Fourth, accumulation of extravascular lung water lowers end-expiratory lung volume by increasing elastic lung recoil as well as stimulating juxtacapillary receptors to drive ventilation. Edema formation around the upper airway may also be important in the predisposition to upper airway closure seen in congestive heart failure.²⁴ Thus, both obstructive and central sleep apnea can develop in these patients due to unstable ventilatory control as well as impaired pharyngeal mechanics.

Application

The treatment of sleep-disordered breathing in congestive heart failure is focused on therapy for the underlying heart failure. Medications to promote diuresis and lower cardiac afterload can reduce the predisposition to unstable breathing. Diuretic therapy can reduce extravascular lung water, left atrial pressure, and upper airway edema. Angiotensin-converting enzyme inhibitors can improve cardiac function thus leading to lower cardiac filling pressures and improved

pulmonary edema via increased forward flow. Other therapies such as oxygen and acetazolamide can help to stabilize breathing,²⁵ particularly for patients with elevated loop gain. This effect can be mediated through a reduction in loop gain, itself probably due to a reduction in the sensitivity of the ventilatory control system (i.e., controller gain, see [Fig. 85-6](#)). Nasal continuous positive airway pressure therapy can benefit some patients, although disordered breathing frequently persists.²⁶ In theory, positive airway pressure should be beneficial for these patients because it can reduce cardiac preload as well as afterload. Multicenter trials assessing the impact of positive-pressure therapy on clinical outcome are ongoing. The data thus far are suggestive, but not definitive, that treatment of obstructive or central sleep apnea is beneficial for patients with congestive heart failure.

AGING

Aging is a major risk factor for both obstructive and central sleep apnea. Other than for children, who have risk of obstructive sleep apnea if they have adenotonsillar hypertrophy, obstructive sleep apnea increases in prevalence with increasing age. For women, menopause is a risk factor whereas, in men, obstructive sleep apnea becomes increasingly common with advanced age. Central sleep apnea is uncommon in children and also increases in prevalence with increasing age. However, the mechanisms underlying these observations are unclear.

Principle

Aging influences many of the physiologic traits underlying sleep apnea. Aging has been associated with impairment in many reflexes important to the upper airway patency; one such reflex is the *negative pressure reflex* that increases pharyngeal dilator muscle activity in response to subatmospheric airway-collapsing pressures.²⁷ Such reflex impairments plus loss of tensile tissue strength over time both likely contribute to the observed increase in collapsibility of the pharyngeal airway during sleep in older compared with younger individuals. Because fat also tends to deposit preferentially around the upper airway with aging, the parapharyngeal fat pads are increased in size in older versus younger individuals, independent of overall body weight. Aging is also known to reduce lung elastic recoil, although the impact of this finding on pharyngeal mechanics remains unclear. Regarding control of breathing, several studies have shown no major impact of aging on overall loop gain,²⁸ although ongoing research is further examining this issue.

Application

Given that the mechanisms underlying sleep apnea in older individuals may be different from those in younger individuals, there may be clinical implications to these findings. For example, an individualized approach to therapy may target an impaired negative pressure reflex in an older individual by pharmacologic manipulation of its sensory or central neural components, whereas other approaches may be more fruitful in younger obstructive sleep apnea patients. In addition, because the mechanisms underlying apnea may differ in older individuals, the adverse consequences

may well be different in older than in younger obstructive sleep apnea patients. For example, esophageal pressures become less negative in older obstructive sleep apnea patients compared to younger patients,²⁹ presumably due to aging-related differences in either the arousal threshold or the ventilatory drive. Because esophageal pressure is a surrogate for the pressure outside the heart, it would be predicted that transmural cardiac pressures (and hence cardiac wall stress/afterload) would be lower in older than in younger obstructive sleep apnea patients. Such pathophysiologic findings may help explain the apparent lack of consequences to obstructive sleep apnea in older compared to younger patients.³⁰ Indeed, sleep apnea in older adults may be a different condition than in younger individuals, with different underlying causes, consequences, and therapeutic approaches.

OTHER CLINICAL CONDITIONS

The majority of respiratory disorders show deterioration in gas exchange during sleep. The integrative physiologic principles and mechanisms underlying this worsening in sleep are explained in “[Integrative Physiologic Mechanisms Underpinning Respiratory Dysfunction and Instability in Sleep](#).” Although the neurobiologic basis underlying the observed abnormalities is less well understood, several principles can be discussed further regarding hypoventilation syndromes, neuromuscular disease, and parenchymal lung disease.

Principles

At least three factors are likely critical to the deterioration of gas exchange that is frequently observed during sleep in patients with respiratory disorders. First, the behavioral influences or the wakefulness stimulus to breathing introduced in “[Integrative Physiologic Mechanisms Underpinning Respiratory Dysfunction and Instability During Sleep](#)” and [Figure 85-5](#) are withdrawn upon transition from wakefulness to non-REM sleep. Accordingly, with the onset of sleep, the drive for ventilation is reduced almost immediately. As a result, arterial PCO_2 levels tend to rise in sleep, and hypoventilation tends to get worse in patients with respiratory acidosis. During REM sleep, however, the behavioral influences may be restored to some extent compared to non-REM sleep, leading to improvement in gas exchange in some patients (see “[Breathing Is Dependent on Feedback Regulation in Sleep](#)”). Second, as discussed earlier, the upper airway narrows during non-REM sleep so that controller gain as defined by chemoresponsiveness is reduced. This reduction of controller gain leads to lower minute ventilation for any given increase in arterial PCO_2 . Third, during REM sleep, there is atonia of the accessory muscles of respiration so that patients reliant on these muscles become more dependent on diaphragmatic activity to achieve ventilation. For some patients, REM sleep thus leads to marked hypercapnia and hypoxemia due to a concomitant decrease in chemosensitivity compared to non-REM sleep (see “[Chemoreceptors and Chemoreflexes](#)”). End-expiratory lung volume also decreases in various stages of sleep, likely as a function of decreased motor output to the muscles of the chest wall, leading to a reduced functional residual capacity and increased propensity for oxygen desaturation and

unstable breathing by alterations in plant gain (see “[Loop Gain and Its Importance](#)”).

Application

The aforementioned conditions lead to deterioration of gas exchange in patients with most respiratory conditions including those with hypoventilation, neuromuscular disease, and parenchymal lung disease.

Hypoventilation. Patients with baseline hypercapnia often experience worsening hypercapnia during non-REM sleep. The effect of REM sleep is quite variable, however, in that some patients such as those with central congenital hypoventilation syndrome actually see improvement in gas exchange during REM sleep. On the other hand, some hypoventilation patients such as those with obesity hypoventilation may experience further worsening of gas exchange during REM sleep than in non-REM sleep. In general, bilevel ventilation is effective at maintaining gas exchange during non-REM and REM sleep in hypoventilation patients. Various respiratory stimulants have also been considered but in general the results have been disappointing.

Neuromuscular Disease. Patients with neuromuscular disease also experience deterioration of gas exchange during non-REM sleep with further worsening during REM sleep. The loss of the wakefulness stimulus, the compromise of upper airway motor tone, the atonia of the accessory respiratory muscles during REM sleep, and the fall in functional residual capacity may all contribute to respiratory compromise in these patients. Treatment of these patients involves addressing the underlying cause (if possible) and using bilevel noninvasive ventilation as part of supportive care.

Parenchymal Lung Disease. In patients with parenchymal lung disease, such as emphysema or pulmonary fibrosis, similar mechanisms can underlie the worsening gas exchange experienced during non-REM and REM sleep. Treatment is again supportive; treatment should also address the underlying lung disease to the extent possible. A subset of patients also exists with the so-called overlap syndrome, which consists of the combination of chronic obstructive pulmonary disease with obstructive sleep apnea. These patients are known to have excess cardiovascular mortality although no clinical trials to date have addressed the optimal treatment of such overlap patients.

INDIVIDUALIZED THERAPY TARGETING UNDERLYING MECHANISMS

The current treatment of choice for obstructive sleep apnea is nasal continuous positive airway pressure. This treatment option has excellent efficacy, but is often poorly tolerated, leading to variable results in clinical practice. Alternative therapies exist but these also have limited effectiveness and can be both expensive and cumbersome for the patient. As a result, many investigators have advocated for further mechanistic-based research to define new therapeutic

approaches based on the individual predisposition to sleep-disordered breathing. The appreciation for the multifactorial nature of obstructive sleep apnea³¹ has opened the way to treatment for this disorder based on underlying mechanisms; for example, there may be anatomic abnormalities at the level of the soft palate (the velopharynx) or behind the tongue (the retroglossal air space). Clinical studies show that the upper airway almost always collapses at the level of the velopharynx in patients with obstructive sleep apnea, but in about half of these patients the obstruction also extends caudally to the retroglossal air space.³² In REM sleep, the lower level of the obstruction can extend to even more caudal levels compared with non-REM sleep, most likely due to the greater suppression of pharyngeal muscle activity in REM sleep. For those individuals with a primary problem of velopharyngeal compromise, palatal surgery such as uvulopalatopharyngoplasty would be predicted to have reasonable efficacy, but less so for individuals with retroglossal airway collapse.

For those individuals with obstructive sleep apnea driven primarily by elevated loop gain, interventions that effectively lower loop gain, such as inhaled oxygen or oral acetazolamide would be predicted to improve respiratory abnormalities. Some individuals may have a primary problem of upper airway muscle tone in sleep and/or reflex compensatory responses; such individuals may respond to pharmacological approaches to increase hypoglossal output³³ or potentially to hypoglossal nerve stimulation.³⁴ Individuals who have multiple predisposing factors contributing to obstructive sleep apnea may benefit from combinations of therapies to resolve the underlying abnormalities. The potential for an individualized approach to obstructive sleep apnea therapy based on underlying mechanisms has received attention using the concept of personalized medicine. This concept can be applied to the spectrum of respiratory abnormalities during sleep.

Key Points

- Obstructive sleep apnea is common, resulting in major neurocognitive and cardiovascular consequences. Combinations of upper airway anatomic abnormalities, instabilities in ventilatory control, and variations in upper airway dilator muscle control all contribute to the predisposition to upper airway obstruction within an individual.
- Non-REM sleep plus sedative- and anesthetic-induced neurodepressive brain states are associated with reduced hypoglossal motor output that can contribute to upper airway obstruction, particularly in individuals who are anatomically predisposed.
- REM sleep is associated with generalized skeletal muscle atonia that also affects the tone in the upper airway dilators such as the genioglossus. Mechanisms of genioglossus muscle atonia are thought to include withdrawal of excitatory inputs from wakefulness-

dependent cell groups and active inhibition mediated through a muscarinic receptor pathway coupled to G protein-coupled potassium channels.

- Opioid narcotics contribute to central apneas and respiratory depression by activating opioid receptors and thereby suppressing the output from the pre-Bötzinger complex. The pre-Bötzinger complex is a key source of respiratory rhythm generation that drives the expression of rhythmic activity in other components of the respiratory network.
- Opioid narcotics can also contribute to severe respiratory depression in sleep by blunting the tonic excitatory stimulation of wakefulness to the respiratory network, especially in those with sleep-disordered breathing who are dependent on such tonic behavioral inputs.
- Obesity contributes to obstructive sleep apnea primarily through anatomic effects on the upper airway and the chest wall, although influences of adipocytokines on ventilatory control may also be important.
- Loop gain is an engineering term used to describe the predisposition to instability in a feedback control system. Elevated loop gain defines a system that is prone to instability, that is, one that can develop periodic behavior with even minor perturbations. Congestive heart failure is associated with elevated loop gain. As a result, heart failure patients frequently experience sleep apnea.
- Aging is associated with impaired protective upper airway reflexes and anatomic changes that may make the pharyngeal airway vulnerable to collapse. Older obstructive sleep apnea patients may have altered consequences of this disorder since the underlying pathophysiology of their condition can be different from that in younger obstructive sleep apnea patients. For example, lesser swings in subatmospheric intrathoracic airway pressures in older versus younger patients may reduce cardiovascular risk through reduced cardiac wall stress.

INTRODUCTION

Carbon dioxide (CO₂) is produced during aerobic cellular respiration and is a “waste product” produced by all aerobic life forms. Arterial CO₂ tension (arterial PCO₂) represents the balance between CO₂ produced, the CO₂ eliminated, and in some cases inspired (either rebreathed or directly added to the breathing circuit) CO₂. Inspired CO₂ (FICO₂) is usually negligible, while alterations in CO₂ production are an unusual—but possible—contributor to systemic CO₂ tension. As an example, CO₂ production increases in hypermetabolic states such as fever or thyrotoxicosis; however, these are generally offset by modest increases in alveolar ventilation, sufficient to normalize the arterial PCO₂. Therefore, for practical purposes, the most important determinant of arterial PCO₂ is its rate of elimination.

Hypocapnia remains a common—and generally underappreciated—component of many disease states, including early mild asthma, high-altitude pulmonary edema, and acute lung injury. In addition, deliberate induction of hypocapnia remains a common, if controversial, practice in both adults and children with acute brain injury, as a strategy to control raised intracranial pressure. In contrast, hypercapnia has historically been avoided by clinicians, with high tidal volumes and minute ventilation

employed to normalize arterial PCO₂, in an effort to keep it within a “normal physiologic” range.

Advances in current understanding of the biology of CO₂ have prompted the idea that hypocapnia or hypercapnia may play roles in the development of acute organ dysfunction or injury.¹ In preclinical models, deliberate hypercapnia may protect against lung and systemic organ injury, beyond effects of reduced tidal volume. In addition, hypocapnia may exert independent harmful effects. Limited clinical data suggest potential beneficial effects of hypercapnia in patients exposed to high lung stretch. This chapter reviews the current clinical status of hypocapnia and hypercapnia in health and disease, discusses the insights gained from basic studies of CO₂, identifies key unresolved concerns regarding hypocapnia and hypercapnia, and considers the potential clinical implications for the management of patients with lung disease.

REGULATION OF ARTERIAL CO₂ TENSION

In health, arterial PCO₂ is tightly regulated via a feedback loop between CO₂ tension and alveolar ventilation. CO₂

has a fundamental role in regulating and controlling breathing, and hypercapnic acidosis is a potent ventilatory stimulant. Type I glomus cells in the carotid body near the bifurcation of the carotid artery and chemosensitive neurons in numerous brain stem regions respond to changes in pH and arterial PCO₂. During normal tidal respiration, the carotid chemoreceptors are critical for maintaining stable arterial PCO₂ levels.^{1a} The response time of the peripheral chemoreceptors to transient changes in arterial PCO₂ is more rapid than that of the central neurons²; however, the central chemosensitive neurons exert a quantitatively larger contribution to stimulating ventilation in response to hypercapnia.³

The effect of alterations in arterial PCO₂ on ventilation is—at least in part—pH dependent, via the production of protons following its spontaneous and carbonic anhydrase-catalyzed combination with water to form carbonic acid, which in turn dissociates to form bicarbonate (HCO₃⁻) and H⁺ ions. Changes in CO₂ and CO₂/H⁺ levels are sensed in special chemosensitive neurons in the carotid body and in several regions of the hindbrain,^{4,5} although it is not certain whether these cells detect pH, CO₂, HCO₃⁻, or a pH gradient across the cell membrane. Nonetheless, the ventilatory response to hypercapnia is greater than that to metabolic acidosis,^{6,7} suggesting the existence of a CO₂ receptor. The peripheral chemoreceptors appear to respond primarily to alterations in arterial PO₂ and H⁺ concentrations, and their function is to maintain arterial PO₂ and H⁺ concentrations constant. The central chemoreceptors appear to respond primarily to alterations in CO₂/H⁺ levels and act to maintain the H⁺ concentration of the cerebrospinal fluid constant. Any acute change of H⁺ in these compartments is counteracted almost instantly by alterations in pulmonary ventilation and more slowly corrected by the kidney.⁸

CAUSES OF ALTERED ARTERIAL CO₂

Arterial PCO₂ is usually expressed in terms of a relationship among CO₂ production, CO₂ elimination, and rarely, a contribution from inspired CO₂ (FiCO₂ is usually close to zero).

$$PaCO_2 \propto \frac{CO_2 \text{ production}}{CO_2 \text{ elimination}} + \text{inspired } [CO_2]$$

ACCIDENTAL HYPERCAPNIA OR HYPOCAPNIA

Accidental hypercapnia is reported most commonly in the operating room or the intensive care unit, and is due to errors associated with mechanical ventilation. The key errors are those that result in hypoventilation, such as circuit disconnection or inadequate minute ventilation. Alternatively, expired gas (which contains approximately 5% CO₂) can be rebreathed as a result of circuit malconnection or depletion of CO₂ absorbers.⁹

Additional causes of acute hypercapnia include hypoventilation secondary to drug-induced respiratory depression,¹⁰ or severe airways obstruction such as status asthmaticus¹¹ or massive aspiration (e.g., grain inhalation).¹² Increased

dead space (e.g., pulmonary embolism) will result in decreased alveolar ventilation and hypercapnia if the minute ventilation is fixed (e.g., the patient is paralyzed on mechanical ventilation), although in most cases, the patient will increase minute ventilation to maintain CO₂ in the normal or slightly low range. Chronic hypercapnia may result from progressive restrictive or obstructive lung diseases such as pulmonary fibrosis or chronic obstructive airways disease or obstructive sleep apnea. Increases in CO₂ production can result from hypermetabolic states such as fever, sepsis, malignant hyperthermia, thyroid crisis, or sometimes overfeeding. In addition, use of bicarbonate buffers (NaHCO₃) results in generation of excess CO₂. Finally, significant increases in CO₂ production will directly increase arterial PCO₂ if the alveolar ventilation is not increased; however, even a slight increase in alveolar ventilation will easily compensate for this.

In the setting of mechanical ventilation, accidental hypocapnia might be more common than accidental hypercapnia, especially in the absence of end-tidal CO₂ monitoring, such as outside the operating room. In one study, severe hypocapnia (end expired CO₂ < 30 mm Hg) was found in 70% of patients transferred by helicopter to a U.S. trauma center.¹³ In children, accidental hypocapnia readily develops during high-frequency ventilation or during extracorporeal support (e.g., *extracorporeal membrane oxygenation* [ECMO], cardiopulmonary bypass).¹⁴⁻¹⁶

PERMISSIVE HYPERCAPNIA

Permissive hypercapnia refers to the elevated arterial PCO₂ that results from hypoventilation of mechanically ventilated patients that is aimed at reducing ventilator-associated lung injury (e.g., *acute respiratory distress syndrome* [ARDS], status asthmaticus).

Deliberate hypoventilation was initially described in 1984 by Darioli and Perret,¹⁷ wherein a series of 29 mechanically ventilated patients (34 episodes of ventilation) with status asthmaticus were managed with deliberate hypoventilation (resulting in severe hypercapnia) with the goal of reducing barotrauma. There were no fatalities in the series, which was very unusual at the time for intubated patients with status asthmaticus. The following year, Wung and colleagues¹⁸ described a series of 15 neonates with persistent pulmonary hypertension of the newborn. This case series was remarkable given that, up to then, vigorous hyperventilation (to achieve hypocapnia in an attempt to reduce the pulmonary vascular resistance) was considered a vital aspect of management; in such cases, death was common and chronic lung disease the rule. There were no deaths in the series of Wung and colleagues¹⁸ and only a single case of chronic lung disease.

Subsequently, the term “permissive hypercapnia” was coined by Hickling and associates¹⁹ in their seminal descriptions of improved survival in ARDS in which plateau pressures and tidal volumes were limited.^{19,20} In all these series, hypercapnia was tolerated (permissive); it was not specifically induced. Rather, the aim was to diminish barotrauma from excessive tidal volumes and airway pressure, and the hypercapnia was simply a result of this strategy. Nonetheless, because of these advances, clinicians became more accepting of hypercapnia in critically ill patients.

DELIBERATE HYPERCAPNIA OR HYPOCAPNIA

Historically the administration of inspired CO_2 was used to hasten emergence from anesthesia; the idea was that stimulation of spontaneous ventilation enhanced clearance of inhaled volatile anesthetic gases (of course increasing minute ventilation using the mechanical ventilator would equally clear the volatile gases, but would result in profound hypocapnia and therefore prolonged apnea). Such administration of inhaled CO_2 at the end of anesthesia was originally termed *de-etherization*,²¹ and the practice was discontinued in the 1980s, largely because of concerns with inadvertent hypercapnia.

More recent clinical studies confirm that therapeutic hypercapnia hastens emergence from anesthesia, even with the more insoluble modern anesthetic agents,²² and capnography—not available in the 1980s—can help avoid excess hypercapnia. Such hypercapnic hyperpnea in spontaneously breathing patients can reduce by half the required recovery time from anaesthesia²³ and could have benefits for postoperative cognitive function and operating room efficiency.

Therapeutic hypercapnia refers to the concept that elevated CO_2 may have specific benefits in critical illness, beyond benefits resulting from lessening barotrauma. If this concept proves to be clinically applicable, then “therapeutically” elevating arterial PCO_2 might be beneficial in ARDS, in addition to tidal volume reduction. Whereas there is some pre-clinical evidence to suggest benefit for hypercapnia in specific experimental models, this approach has not been directly tested in critically ill patients.

In contrast, *therapeutic hypocapnia* is often used in the management of acute brain injury in both adults and children.²⁴⁻²⁶ Hypocapnia is induced to lower *intracranial pressure* (ICP) by decreasing the cerebral blood volume through cerebral artery vasoconstriction. Because elevated ICP is generally adverse and hypocapnia has traditionally been thought to be benign, hyperventilation has been widely practiced in patients with acute brain injury, even in the absence of elevated ICP.²⁶ This reasoning led to the idea that more profound hyperventilation might be even better, and sometimes extremes of hypocapnia were advocated for acute brain injury,²⁷⁻³¹ although more recently this concept has been discredited.

TRANSPORT OF CO_2 IN THE BLOOD

The vast bulk of CO_2 is produced in the mitochondria, where cellular CO_2 concentrations are highest. The pathway for transportation, involving step-wise decreases in CO_2 partial pressure gradients, originates in the mitochondria and proceeds through the cytoplasm, cell membranes, capillaries, venules, larger veins, and ultimately into the mixed venous blood before elimination through the alveoli.

Transportation of CO_2 in the blood is accomplished via three different mechanisms with the exact proportions carried by each mechanism varying depending on whether it is arterial or venous blood.³² Dissolved CO_2 in plasma, reported as arterial PCO_2 (i.e., partial pressure) accounts for

only 5% to 10% of the total CO_2 transported in blood. Almost 90% of total CO_2 in the blood is converted to bicarbonate ions (HCO_3^-), almost all catalyzed by carbonic anhydrase within the red blood cells. The remainder (5% to 10%) is transported as carbamino-hemoglobin, in which CO_2 is bound to terminal amino groups in *hemoglobin* (Hb) molecules.³² The usual amount of CO_2 in the arterial blood is 21.5 mmol per liter of blood, with slightly more (23.3 mmol/L) in venous blood. Overall, more than 80% of the CO_2 is carried within the red blood cells.

OXYGEN-INDUCED HYPERCAPNIA

CO_2 transport in the blood is altered by oxygen, leading to an elevated PCO_2 ; this oxygen-induced hypercapnia is seen in patients with end-stage lung disease who inhale supplemental O_2 . The mechanism of oxygen-induced hypercapnia was formerly thought to be oxygen-induced inhibition of ventilatory drive in patients thought to be critically dependent on hypoxic ventilatory drive. In fact, minute ventilation is not diminished in such patients.^{33,34} The mechanism is now better understood as having three key components: the Haldane effect, impaired hypoxic pulmonary vasoconstriction, and inability to increase minute ventilation.³⁵

The *Haldane effect*³⁶ is the term given to the phenomenon whereby increasing arterial PO_2 reduces the ability of the blood to store CO_2 (as Hb-bound, carbamino Hb; or as HCO_3^-), thereby increasing the CO_2 partial pressure. There are two elements to the Haldane effect. First, increased arterial PO_2 decreases formation of carbamino compounds; this reduces the quantity of CO_2 bound to Hb, thereby elevating the dissolved CO_2 (PCO_2). Second, histidine is important for the buffering properties of Hb; it contains an imidazole group that, at physiologic pH, is an effective buffer of H^+ ions but is also an important molecular link between heme groups and the Hb chains. Elevated PO_2 results in greater quantities of O_2 bound to Hb, which causes allosteric modifications of the Hb conformation. These conformational changes impact the heme-linked histidine and reduce its ability to buffer H^+ ion; with less H^+ buffering by Hb, there is more H^+ binding to HCO_3^- and release of stored CO_2 .

In patients with end-stage lung disease, hypoxic pulmonary vasoconstriction is an important mechanism to divert pulmonary artery blood from poorly ventilated regions (see Chapters 4 and 6). Increasing arterial PO_2 inhibits hypoxic pulmonary vasoconstriction, thus pulmonary artery blood containing CO_2 is diverted to less well-ventilated regions, and the efficiency of CO_2 excretion is impaired. Finally, while most patients would easily compensate for the increased PCO_2 with minimal increases in minute ventilation, this is not possible in many patients with end-stage lung disease.

MOLECULAR EFFECTS OF CO_2

ACID BASE AND IONIC BALANCE

CO_2 plays a key role in acid-base regulation, because the bicarbonate- CO_2 buffer system is the predominant buffer in the bloodstream. During metabolic acidosis, excess H^+ ions in the blood combine with HCO_3^- to form the weak

(carbonic) acid H_2CO_3 . Hypercapnia generally results in acidosis, by combining with water to form carbonic acid, which in turn dissociates to form bicarbonate (HCO_3^-) and H^+ ions. The protons thus generated can react with titratable groups in certain amino acids, resulting in structural changes in many proteins and enzymes in cell membranes and cellular aqueous environments.³⁷ Because acidosis suppresses most cellular functions, the body uses a number of strategies to defend its intracellular and extracellular pH within remarkably narrow limits.³⁸ The intracellular acidosis produced by hypercapnia may be corrected within a few hours, as opposed to 1 to 2 days needed for renal compensation.³⁹ This buffering is accomplished via active cell membrane ion transporters that extrude protons and exchange them for extracellular sodium.

CO_2 has effects on intracellular and extracellular ion concentrations. Following the onset of hypocapnia, there is rapid efflux of hydrogen ions; this compensatory mechanism is exhausted easily and, if hypocapnia persists, systemic alkalosis develops. The kidney effects a more efficient compensatory mechanism, reducing its hydrogen ion excretion and increasing bicarbonate loss, as well as decreasing excretion of ammonium.⁴⁰ During (hypocapnic) alkalemia, movement of H^+ from intracellular to extracellular space is accompanied by an opposite movement of K^+ (and Na^+) into the cell, although the resulting hypokalemia is usually modest.⁴¹ In addition, phosphate moves into the cell because of increased cellular phosphorylation.⁴² During alkalemia, albumin releases bound H^+ , swapping it for Ca^{2+} , and lowering the ionized calcium fraction,⁴³ which may be severe.⁴⁴

PROTEIN FUNCTION AND METABOLIC EFFECTS

CO_2 molecules can bind directly with free amine groups in proteins to form carbamate residues.⁴⁵⁻⁴⁷ This binding of CO_2 also modifies protein structure and function and may account for some of the observed differences in the effects of acidosis caused by CO_2 compared to acidosis resulting from other causes. The Bohr effect, wherein increased arterial PCO_2 results in a rightward shift of the hemoglobin-oxygen dissociation curve, resulting in a lowered affinity of Hb for O_2 and facilitation of oxygen unloading at the tissues, is a good example of this phenomenon.

One consequence of intracellular alkalosis is activation of glycolysis due to inhibition of the rate-limiting enzyme phosphofructokinase.⁴⁸ A feedback system functions as a mechanism to generate H^+ ions to counter intracellular alkalosis, whereby lactic acid production is increased by alkalemia (and decreased by acidemia).⁴⁹

RESPIRATORY SYSTEM EFFECTS

PULMONARY VASCULATURE

The effects of CO_2 on the pulmonary vasculature contrast with those in the systemic circulation. Hypercapnia can increase pulmonary vascular pressure by increasing both cardiac output and pulmonary vascular resistance⁵⁰ (Table 86-1). While hypercapnia increases pulmonary arterial pressure and pulmonary vascular resistance, this effect might not be as significant in preexisting pulmonary hypertension.⁵¹ Hypercapnia is a less potent pulmonary vasocon-

strictor than hypoxia, and its more important effect may be in augmenting hypoxic vasoconstriction.³⁷ While relatively little is understood about the cellular mechanism of CO_2 -induced pulmonary vasoconstriction, much of this effect appears to be catecholamine-mediated.⁵²

Hypocapnic alkalosis produces pulmonary vasodilation,⁵³ which is commonly used to reduce elevated pulmonary artery pressure, particularly in the setting of congenital heart disease and persistent pulmonary hypertension of the newborn (Table 86-2).

AIRWAY RESISTANCE AND LUNG COMPLIANCE

CO_2 can impact airway tone, with hypocapnia producing bronchoconstriction and hypercapnia causing bronchodilation in isolated airway preparations.^{54,55} Hypercapnia has been variably reported to either increase⁵⁶ or decrease⁵⁷ airway resistance. This paradox may be explained by direct dilation of small airways and indirect—vaguely mediated—large airway constriction. Indeed, in spontaneously breathing unanesthetized subjects, the CO_2 -related changes of respiratory mechanics are entirely caused by upper airway resistance.⁵⁶ In mechanically ventilated subjects, hypercapnia may decrease airway resistance,⁵⁸ although opposing actions of CO_2 may result in little net change in airway resistance.⁵⁹

Parenchymal lung compliance increases in response to hypercapnic acidosis, arising from active relaxation in response to increased alveolar CO_2 ⁶⁰ or due to increased surfactant secretion or more effective surface tension-lowering properties under acidic conditions.⁶¹

GAS EXCHANGE

In the normal lung, CO_2 modifies pulmonary vascular and airway tone. Increasing alveolar PCO_2 causes bronchodilation, while increasing pulmonary arterial PCO_2 increases pulmonary vascular resistance. The physiologic role of these contrasting effects of CO_2 on bronchial versus pulmonary arterial smooth muscle tone is to facilitate matching of regional ventilation and perfusion. For example, pulmonary artery occlusion results in regional hypocapnia, which results in bronchoconstriction,^{62,63} thereby directing airflow away from these unperfused alveoli. By this same mechanism, CO_2 administration improves matching of ventilation and perfusion and increases arterial oxygenation in both normal⁶⁴⁻⁶⁶ and injured⁶⁷ lungs.

Alveolar CO_2 can alter distribution of ventilation among acini and larger lung units,⁶⁸ as well as augment global ventilation-perfusion matching,^{64,69} which leads to improved gas exchange.⁷⁰ A dose-response relationship exists between FICO_2 and arterial PO_2 .^{65,66} However, in ARDS, permissive hypercapnia (produced via lowering tidal volume) is associated with increased shunt, although this is likely due to atelectasis from low tidal volumes.⁷¹

Severe hypocapnia produces bronchoconstriction,⁵⁶ reduces collateral ventilation,^{72,73} and impairs parenchymal lung compliance.⁶⁰ Hypocapnia also attenuates hypoxic pulmonary vasoconstriction and increases intrapulmonary shunting.⁶⁴ The overall effect can be a net decrease in arterial PO_2 .

Hypocapnic alkalosis impairs pulmonary capillary permeability in the rodent isolated lung.⁷⁴ In contrast,

Table 86-1 Effects of Hypercapnia

Organ System	Physiologic Effects	Pathophysiologic Consequences
Cardiovascular	Cardiac output and myocardial perfusion Increased cardiac output Direct reduction in cardiac contractility ¹²⁸ Counterbalanced by indirect sympathoadrenal effects (increased preload, heart rate, myocardial contractility) and decreased afterload (reduced vascular tone) ¹²⁹ Coronary vasodilation, mainly mediated by nitric oxide ¹³⁰	Improved cardiac output and oxygen delivery to tissues ¹²⁹
	Systemic oxygen delivery Rightward shift of hemoglobin-oxygen dissociation curve (Bohr effect) ¹³⁴ May acutely increase hematocrit ¹³¹	Improved oxygen delivery and unloading in tissues ¹³³
	Oxygen demand HCA reduces cellular respiration and oxygen consumption ¹³²	Reduction in tissue O ₂ demand
Respiratory	Control of respiration Changes in CO ₂ /H ⁺ levels sensed in special chemosensitive neurons in the carotid body and in hindbrain ^{4,5}	Oxygen-induced hypercapnia (see text for mechanism)
	Pulmonary vascular resistance Increased cardiac output and pulmonary vascular resistance ⁵⁰ Augments hypoxic pulmonary vasoconstriction ³⁷	Acute hypercapnia can worsen pulmonary hypertension Enhances ventilation-perfusion matching
	Airway resistance Direct dilation of small airways ⁵⁷ Indirect—vagally mediated—large airway constriction ⁵⁶	Opposing actions of CO ₂ may result in little net change in airway resistance ⁵⁹ Contribution to ventilation-perfusion matching (e.g., during pulmonary embolism)
	Lung compliance Increased surfactant secretion ⁶¹ Increased parenchymal compliance ⁶⁰	Improved lung compliance
	Gas exchange CO ₂ modifies pulmonary vascular and airway tone to help match regional ventilation and perfusion	Improved matching of ventilation and perfusion Increased arterial oxygenation by this mechanism in both normal ⁶⁴⁻⁶⁶ and injured ⁶⁷ lungs
Neurologic	Intracranial pressure Increased cerebral blood flow and volume ⁹⁰	Increased intracranial pressure
	Cerebral oxygenation Increased cerebral blood flow ⁹⁰ Increased cerebral oxygenation ²⁶³	Increased cerebral oxygenation—potential benefit in ischemic states ²⁶²
	Cerebral oxygen demand Decreases central nervous system O ₂ demand ²⁶³	Improved cerebral oxygen supply-demand ratio ²⁶³
Inflammation and immunity	Neutrophil and macrophage function Inhibition of neutrophil and macrophage migration and adhesion ¹⁷¹ Decreased secretion of important proinflammatory cytokines (e.g., TNF- α , IL-8, IL-6) ¹⁵² Inhibits phagocytosis and intracellular killing of bacteria (by reduction of nicotinamide adenine dinucleotide phosphate-oxidase activity) ¹⁷⁷	Reduced host response to injury Reduced proinflammatory response Potential increased susceptibility to prolonged sepsis
	Free radicals Decreased xanthine oxide free radical generation ¹⁶² Decreased production of NO-derived radicals (NO ₂ , NO ₃) and may shift the balance from O ₂ -derived toward N ₂ -derived (i.e., nitration) reactions ¹⁶⁵	Reduced free radical mediated injury Reduced microbicidal efficacy
Metabolic	Intracellular metabolism Intracellular acidosis causes inhibition of glycolysis due to inhibition of the rate-limiting enzyme phosphofructokinase ⁴⁸ Feedback system whereby lactic acid production is decreased by acidemia ⁴⁹	Decreased metabolism—potentially beneficial in ischemic states Decreased metabolic demand

hypercapnia reduces alveolar fluid clearance in healthy isolated perfused lungs by endocytotic withdrawal of Na⁺/K⁺-ATPase from the basolateral membrane of alveolar epithelial cells.⁷⁵ Whether this is the case *in vivo* or in injured lungs remains to be determined.

DIAPHRAGMATIC FUNCTION

The effects of hypercapnia on the diaphragm are complex and incompletely understood. Hypercapnia has been demonstrated to impair diaphragmatic function in preclinical

studies in which alveolar ventilation was not controlled. Rats exposed to prolonged environmental hypercapnia (7.5% CO₂ for 6 weeks) demonstrate significantly depressed diaphragmatic muscle function, as well as altered diaphragmatic composition with increased slow-twitch and decreased fast-twitch fibers.⁷⁶ In fact, even 15 minutes of exposure to 7% inspired CO₂ may transiently⁷⁷ and reversibly⁷⁸ impair neuromuscular function. In contrast, in studies in which ventilation is controlled and CO₂ increases moderately, hypercapnia may protect the diaphragm from injury.⁷⁹ Thus it remains unclear whether any deleterious

Table 86-2 Effects of Hypocapnia

Organ System	Physiologic Effects	Pathophysiologic Consequences
Cardiovascular	Cardiac output and myocardial perfusion Reduced cardiac output Increased systemic vascular resistance ¹⁴⁰ Hyperventilation additionally impairs venous return ¹⁴² Decreased myocardial blood flow, independent of myocardial workload ¹³⁹ Increased myocardial oxygen extraction (as a result of hyperventilation) ¹⁴¹	Reduced cardiac output May worsen myocardial ischemic injury
	Systemic oxygen delivery Leftward shift of the hemoglobin-oxygen dissociation curve (increased affinity of hemoglobin for oxygen) ¹³⁴ Compensated to some extent by a rapid increase in lactate production ¹³⁷ and by an increase in the concentration of 2,3-diphosphoglycerate ¹³⁸ over a period of several hours Systemic arterial vasoconstriction decreases global and regional O ₂ supply ^{135,136}	Decreased oxygen delivery to tissues
	Oxygen demand Increased cellular excitation and oxygen demand ¹²⁰	Oxygen supply/demand imbalance
Respiratory	Control of respiration Changes in CO ₂ /H ⁺ levels sensed in special chemosensitive neurons in the carotid body and in hindbrain ^{4,5}	Cheyne-Stokes respiration and central sleep apnea are thought to be due to decreased cerebral chemosensitivity to CO ₂ and left ventricular systolic dysfunction ²⁹¹
	Pulmonary vascular resistance Hypocapnic alkalosis produces pulmonary vasodilation ⁵³	Acute hypocapnia is used to alleviate pulmonary hypertension especially in setting of congenital heart disease and persistent pulmonary hypertension of the newborn Worsens ventilation-perfusion matching
	Airway resistance Direct constriction of small airways ^{54,55}	Contribution to ventilation-perfusion matching, which could be beneficial (e.g., during localized perfusion deficits such as pulmonary embolism), or harmful (e.g., during asthma)
	Lung compliance Increased alveolar permeability, ⁷⁴ decreased compliance, ²³⁷ and reduced surfactant production ²³⁸ These effects can be ameliorated by normalizing alveolar CO ₂ , ^{66,238,239,241} and in some cases prevented by elevated inspired CO ₂ ^{66,163,165,213}	Reduced lung compliance and worsened lung injury
	Gas exchange Worsened bronchoconstriction ⁵⁶ Reduced collateral ventilation ^{72,73} and impaired parenchymal lung compliance ⁶⁰ Attenuated hypoxic pulmonary vasoconstriction and increased intrapulmonary shunting ⁶⁴	Worsens matching of ventilation and perfusion The overall effect can be a net decrease in arterial PO ₂ Attenuation of hypoxic pulmonary vasoconstriction; can worsen intrapulmonary shunt and systemic oxygenation ⁶⁴
Neurologic	Intracranial pressure (ICP) Reduced ICP via arteriolar vasoconstriction and decreased cerebral blood volume	Acute hypocapnia decreases ICP, which is potentially lifesaving where ICP is critically elevated
	Cerebral oxygenation Decreases cerebral blood flow ¹⁰⁸ Decreases systemic oxygenation	Decreases cerebral oxygenation—potentially harmful in ischemic states Cerebral vasoconstriction may reduce overall perfusion ¹¹³ ; in focal ischemia, blood flow to hypoxic regions is selectively lowered ²⁶³ and infarct size increased ^{263,268} Termination of sustained hypocapnia can precipitate cerebral hyperemia and raised intracranial pressure ¹¹⁶
	Cerebral oxygen demand Increased CNS O ₂ demand through increasing neuronal excitability, ²⁶⁹ through increased excitatory synaptic transmission, ²⁶⁹ and by direct effect on the neuronal membrane itself ¹²⁰	Worsens cerebral oxygen supply-demand ratio
Acid-Base	Initial rapid cellular efflux of hydrogen ions (which is exhausted easily) Followed by renal compensatory mechanism: reduced hydrogen ion excretion, increased bicarbonate loss, and decreased excretion of ammonium ⁴⁰	Movement of H ⁺ from intracellular to extracellular space is accompanied by (1) an opposite movement of K ⁺ (and Na ⁺) into the cell (the resulting hypokalemia is usually modest ⁴¹), (2) phosphate movement into the cell due to increased cellular phosphorylation, ⁴² and (3) albumin release of bound H ⁺ , swapping it for Ca ²⁺ and lowering the ionized calcium fraction, ⁴³ which may be severe ⁴⁴
Metabolic	Intracellular alkalosis causes activation of glycolysis due to inhibition of the rate-limiting enzyme phosphofructokinase ⁴⁸ Feedback system whereby lactic acid production is increased by alkalemia ⁴⁹	Increased tissue O ₂ demand

effects of hypercapnia on the diaphragm are due to direct effects of CO_2 or result from diaphragmatic fatigue from the induced increase in ventilation.

CENTRAL NERVOUS SYSTEM EFFECTS

CEREBRAL BLOOD FLOW

The change in *cerebral blood flow* (CBF) during variations of arterial PCO_2 depends on several factors, including baseline CBF, cerebral perfusion pressure, and the presence of anesthesia. Across a broad range of conditions, most studies report an increase in global CBF of 1 to 2 $\text{mL} \cdot 100 \text{ g}^{-1} \cdot \text{min}^{-1}$ for each 1 mm Hg increase in arterial PCO_2 ⁸⁰⁻⁸²; reducing arterial PCO_2 to 20 to 25 mm Hg decreases the global CBF by 40% to 50%, with minimal effect from further arterial PCO_2 reduction. Increasing the arterial PCO_2 to 80 mm Hg produces a maximal increase in CBF of 100% to 200% in anesthetized animals,⁸³ but in the awake state, arterial PCO_2 of 80 mm Hg can increase CBF by up to sixfold; in such cases, one half of the increase in CBF results from release of endogenous catecholamines and activation of neuronal metabolism.⁸⁴ Thus, in awake subjects, severe hypercapnia may increase the flow by two mechanisms: a direct effect of CO_2 on cerebral blood vessels and an indirect effect increasing neuronal metabolic rate and catecholamine release.

However, these effects are not sustained: with hypocapnia for up to 4 hours, CBF recovers to within 10% of baseline⁸⁵ due to reduced cerebrospinal fluid and extracellular HCO_3^- and due to correction toward a normal extracellular pH.

The extent to which CO_2 modulates CBF varies depending on baseline CBF, which is not homogeneous across the brain. Areas of the brain that receive more blood flow have a steeper flow response to changes in arterial PCO_2 . In patients with traumatic brain injury, there is a 3% change in CBF per mm Hg change in arterial PCO_2 ,⁸⁶ but because the response depends on baseline flow, it is reduced in patients with lower CBF.⁸⁶ The regional differences are significant. In the cerebral cortex of the anesthetized cat, the baseline CBF is $86 \text{ mL} \cdot 100 \text{ g}^{-1} \cdot \text{min}^{-1}$, and a 1 mm Hg change in arterial PCO_2 changed CBF by 1.7 mL .⁸¹ In contrast, the spinal cord has a blood flow of $46 \text{ mL} \cdot 100 \text{ g}^{-1} \cdot \text{min}^{-1}$, and each 1 mm Hg change in arterial PCO_2 changed CBF by 0.9 mL .⁸¹ Similar findings have been reported in rabbits⁸² and humans.⁸⁷

HYPOCAPNIA AND CEREBRAL VASOCONSTRICTION

The mechanisms by which arterial CO_2 tension modulates cerebral vasoactivity depend on the size and type of blood vessel. The effects on cerebral vascular tone are mediated via changes in pH rather than CO_2 per se.⁸⁸ The diameter of cerebral arterioles responds only to changes in pH and not to buffered changes in CO_2 tension.⁸⁹ In addition, the effect of CO_2 on cerebrovascular tone is largely confined to the cerebral arterial vasculature, with little effect on associated veins or capillaries.⁹⁰

Hypercapnic acidosis induces precapillary dilation of cerebral arterioles,⁹¹ and whereas all cerebral arteries show some responsiveness to altered CO_2 tension, the larger arteries are less sensitive while the small pial arterioles are most responsive.⁹² Changes in these arterioles are not detected using noninvasive technologies, such as transcranial Doppler, which focuses on the larger vessels.⁹²

Whereas direct and indirect mechanisms mediate the effects of CO_2 on CBF, cerebral vascular tone is altered by CO_2 only via a direct effect on the arteriole wall^{88,93,94} and not by alterations in catecholamine release or sympathetic tone.^{83,95} The vascular endothelium and smooth muscle layer play a central role. Several lines of evidence suggest that endothelial release of *nitric oxide* (NO) in response to alterations in PCO_2 is a key mechanism. Administration of an exogenous NO donor reduces basal cerebrovascular resistance and blunts the cerebral vasoconstrictor effect of hypocapnia in humans.⁹⁶ Damage to cerebrovascular endothelium is associated with impaired CO_2 cerebrovascular reactivity, which parallels impaired release of NO from the endothelium.⁹⁷ Inhibition of NO synthase reduces hypercapnia induced cerebral vasodilation.^{98,99} Specific inhibition of the neuronal isoform of NO synthase reduces hypercapnia induced vasodilation in the parietal cortex¹⁰⁰ and retinal circulation.¹⁰¹

In contrast, in adult rodents, damage to the endothelium *in vivo* does not alter the response of the cerebral arteries to hypercapnia,¹⁰² suggesting alternative pathways. CO_2 ultimately regulates vascular tone by modulating intracellular calcium concentration and sensitivity.¹⁰³ Alkalosis induces increases in concentrations of intracellular calcium in the vascular smooth muscle, increasing the vascular tone.¹⁰⁴ In addition, NO activates guanylate cyclase in vascular smooth muscle, increasing the cyclic guanosine monophosphate concentration,¹⁰⁵ which in turn phosphorylates calcium channels.¹⁰⁶

Elevation of extracellular calcium prevents acidosis-induced dilation of cerebral arterioles, suggesting that reduced vascular smooth muscle calcium reentry may mediate in part the acidosis-reduced vascular tone.⁹³ In addition, opening of potassium channels during acidosis allows egress of potassium, hyperpolarizing the cell, closing voltage-gated calcium channels, and reducing vascular tone by reducing calcium entry.¹⁰⁷

CEREBRAL PERFUSION—FLOW VERSUS VOLUME

The primary aim of inducing hypocapnia in the setting of raised ICP is to reduce cerebral blood volume (Fig. 86-1). However, the effect of CO_2 on cerebrovascular tone is largely confined to the cerebral arteries⁹⁰; thus the effect of changing arterial PCO_2 on CBF is substantially larger than its effect on cerebral blood volume (Fig. 86-2). Fortune and colleagues¹⁰⁸ demonstrated that hypocapnia in volunteers decreased cerebral blood volume by 7% while reducing CBF by greater than 30%. Because low CBF is common in the first 24 hours after traumatic brain injury, there is particular concern for inducing ischemia by hyperventilation.¹⁰⁹ In summary, the cost of hypocapnia in terms of reduced cerebral perfusion may outweigh any benefit in terms of reducing intracranial volume. Even so, hypocapnia remains in

widespread use in the management of patients with acute brain injury²⁶ (Fig. 86-3).

CEREBRAL OXYGENATION

In humans, when arterial PCO_2 is reduced to 20 to 25 mm Hg, CBF is reduced to 20 to 25 mL/100 g \cdot min $^{-1}$,^{110,111} but does not reach lower levels even during extreme hypocapnia in anesthetized (arterial PCO_2 10 mm Hg)¹¹¹ or nonanesthetized humans (arterial PCO_2 16 mm Hg).⁸⁵ In nonanesthetized, normothermic humans and primates, the earliest signs and symptoms of cerebral ischemia, such as confusion, inability to follow commands, focal neurologic deficits, and slowing of the

Figure 86-1 Rationale for the use of hypocapnia in patients with raised intracranial pressure. Because the cranial cavity represents a fixed volume, an increase in the volume of brain tissue due to edema, tumor or hematoma formation can initially be compensated by displacement of volume from another compartment. Acute hypocapnia can reduce cerebral blood volume, thereby temporarily attenuating the rise in intracranial pressure. (From Curley G, Kavanagh BP, Laffey JG: Hypocapnia and the injured brain: more harm than benefit. *Crit Care Med* 38:1348–1359, 2010.)

electric activity of the brain, measured by an electroencephalogram, are seen at global CBF levels of 20 to 30 mL/100 g \cdot min $^{-1}$; however, CBF must be reduced to less than 10 mL/100 g \cdot min $^{-1}$ to cause neuronal cell death.^{112,113}

Hyperventilation can reduce CBF to ischemic levels; in humans and animals, reducing the arterial PCO_2 to 20 to 25 mm Hg slows the electroencephalogram¹¹⁴ and impairs mental function,¹¹⁵ both of which suggest mild cerebral ischemia. Severe hypocapnia also increases *central nervous system* (CNS) lactate, consistent with impaired oxidative metabolism,^{116,117} and cortical PO_2 is reduced during hypocapnia. Indeed, severe hypocapnia (10 mm Hg arterial PCO_2) can reduce cortical PO_2 despite a plateau low level of CBF, indicating that further hypocapnia additionally increases local O_2 consumption or inhibits local delivery.^{118,119} Marked alkalosis also shifts the oxyhemoglobin dissociation curve to the left, which can enhance uptake in the lung, but limits oxygen delivery to systemic organs, including the brain.

Hypocapnia increases neuronal excitability^{120,121} via a direct effect on the neuronal membrane,¹²² which increases cerebral glucose utilization,^{123,124} leads to neuronal glucose depletion, and increases anaerobic metabolism.^{125,126} Also, alkalosis, especially respiratory alkalosis, inhibits the usual negative feedback by which low pH limits production of endogenous organic acids (e.g., lactate) during ischemia.¹²⁷ This may prevent cellular metabolic down-regulation in the setting of diminished nutrient supply, a potentially protective mechanism.

Overall, most studies indicate that, in the normal brain, hypocapnia can reduce CBF to the point of cerebral ischemia but not to levels of CBF that cause rapid neuronal death. If hypocapnia causes cerebral ischemia in the normal brain, it is likely mild and not associated with gross disturbances of brain oxidative metabolism. However, the long-term effect of hyperventilation on the normal brain is not known. Thus, in aggregate, hypocapnia may cause brain

Figure 86-2 Hypocapnia decreases regional cerebral perfusion and increases oxygen extraction in patients following traumatic brain injury. Box and whisker plots of changes (Δ) in cerebral blood flow, cerebral blood volume, cerebral oxygen metabolism, and oxygen extraction fraction produced by hyperventilation, measured in 15 regions of interest in 18 subjects between 2 and 7 days after traumatic brain injury. The central lines in each box denote median values, the lower and upper boundaries the 25th and 75th centile, the error bars the 10th and 90th centile, and the closed circles outlying data points. $\star P < 0.001$, Wilcoxon's signed-rank test with Bonferroni correction, comparing normocapnic and hypercapnic values. (From Coles JP, Fryer TD, Coleman MR, et al: Hyperventilation following head injury: effect on ischemic burden and cerebral oxidative metabolism. *Crit Care Med* 35:568–578, 2007.)

Figure 86-3 Frequency of hypocapnia in adults with traumatic brain injury. The distribution of arterial PCO₂ values in blood gas analyses is skewed toward hypocapnia, with most values in the range of 30 to 35 mm Hg, suggesting that hyperventilation therapy is still in widespread use. Int, intensified. (From Neumann JO, Chambers IR, Citerio G, et al: The use of hyperventilation therapy after traumatic brain injury in Europe: an analysis of the BrainIT database. *Intensive Care Med* 34:1676–1682, 2008.)

ischemia by increasing cerebral oxygen demand as well as decreasing cerebral oxygen supply. These concerns limit the utility of hypocapnia to the setting of life-threatening increases in ICP, where it can be lifesaving by allowing time for definitive intervention.

CARDIOVASCULAR SYSTEM EFFECTS

SYSTEMIC CIRCULATION

Hypercapnic acidosis directly reduces contractility of cardiac¹²⁸ and vascular smooth muscle. This is counterbalanced by the hypercapnia-mediated sympathoadrenal effects of increased preload and heart rate, increased myocardial contractility, and decreased afterload, leading to a net increase in cardiac output.¹²⁹ Hypercapnia results in a complex interaction of altered cardiac output, hypoxic pulmonary vasoconstriction, and intrapulmonary shunt to produce a net increase in arterial PO₂. Because hypercapnia generally elevates cardiac output, global O₂ delivery is increased. Hypercapnic acidosis causes coronary vasodilation, mainly mediated by NO.¹³⁰ Hypercapnia and acidosis shift the hemoglobin-oxygen dissociation curve rightward, reducing the oxygen affinity of Hb, and hypercapnic acidosis may acutely elevate hematocrit by a mechanism that may involve sympathetically mediated autotransfusion,¹³¹ further increasing tissue oxygen delivery. Acidosis may reduce cellular respiration and oxygen consumption,¹³² which may further benefit a supply and demand imbalance. In addition, hypercapnic acidosis increases O₂ tension in both subcutaneous tissues and the intestinal wall.¹³³

Hypocapnia and alkalosis, on the other hand, increase the affinity of Hb for oxygen (leftward displacement of the dissociation curve)¹³⁴ and reduce microcirculatory blood flow,^{135,136} further impairing local oxygen delivery. This is compensated to some extent by a rapid increase in lactate production¹³⁷ and by an increase in the concentration of 2,3-diphosphoglycerate,¹³⁸ which, over a period of several hours, may have an opposite effect on the dissociation curve.

Hypocapnia depresses myocardial blood flow, independent of myocardial workload.¹³⁹ In patients with coronary artery disease, mild hyperventilation slightly increases systemic vascular resistance and reduces cardiac index.¹⁴⁰ In addition, hyperventilation increases myocardial oxygen extraction.¹⁴¹ More pronounced levels of hypocapnia reduce cardiac output,¹⁴² and indirect effects of intrathoracic pressure associated with passive hyperventilation may additionally impair venous return and further depress cardiac output.¹⁴³

SPLANCHNIC EFFECTS OF ALTERED CO₂

Hypercapnia improves regional—including mesenteric—blood flow¹⁴⁴ and enhances peripheral microcirculatory flow,¹⁴⁵ thereby increasing organ oxygen delivery and splanchnic tissue oxygenation. Hypercapnia preserves tissue oxygenation of the gastrointestinal mucosa in uninjured animals,¹⁴⁶ and it reverses decrements in gastric mucosal oxygenation during hemorrhagic shock^{147,148} and following captopril administration.¹⁴⁶

The effects of CO₂ on the splanchnic organs are less well understood. CO₂ and acid-base status modulate splanchnic organ cellular function. Acidosis protects hepatocytes from anoxic¹⁴⁹ or chemical hypoxia-induced cell death,¹⁵⁰ while restoration of normal pH abolishes this protection. This effect may represent a protective adaptation against hypoxic and ischemic stress. In the kidney, acidosis protects isolated renal cortical tubules from anoxia-induced injury.¹⁴⁹ Hypercapnic acidosis, particularly in the setting of concomitant hypoxia, may produce marked sympathetic activation, which can lead to intense renal vasoconstriction and tubular sodium reabsorption, causing depressed glomerular filtration and increased fluid retention.¹⁵¹

INFLAMMATION AND REPAIR

MEDIATOR PRODUCTION

Hypercapnia and acidosis inhibit cytokine signaling in immune effector cells.¹⁵²⁻¹⁵⁵ Acidosis reduces secretion of important proinflammatory cytokines (e.g., TNF- α , IL-8, IL-6) from *polymorphonuclear leukocytes* (PMNs)¹⁵² and macrophages¹⁵⁴; especially important may be the production of IL-8 by PMNs, which is pivotal in mediating the acute inflammatory response to infection.¹⁵² However, the inhibition of PNM IL-8 secretion is blocked by pretreatment with acetazolamide, a drug that lessens the impact of PCO₂ on neutrophil intracellular pH.¹⁵²

CO₂-induced inhibition of cytokines can be sustained. Indeed, peritoneal macrophages had reduced TNF- α production up to 3 days after peritoneal insufflation of CO₂ (as

used during laparoscopic surgery),¹⁵⁶ a phenomenon that may result from inhibition of *nuclear factor-kappa B* (NF- κ B), a regulator of the transcription of mediators in inflammation, injury, and repair.¹⁵⁷

COMPLEMENT ACTIVATION

Innate immunity requires the complement system in order to target pathogens for phagocytosis or lysis; complement is activated by acidosis. Acid activation of C5 combines with C6, forming a lytic complex, C5b6a¹⁵⁸ via the classic activation pathway. The alternative complement pathway is also activated by acidosis with increased activity of C3 convertase, in turn increasing complement binding to—and lysis of—erythrocytes.¹⁵⁹ C3 (and C5) is activated with H⁺ from hypercapnic or lactic acidosis, as well as with hydrochloric acid,¹⁶⁰ and is due to the acidosis per se.¹⁶⁰

FREE RADICAL GENERATION

Hypercapnic acidosis reduces free radical tissue damage in brain¹⁶¹ and lung,¹⁶² as well as following lung ischemia-reperfusion.¹⁶³ It lessens production of NO-derived radicals (NO₂, NO₃) following ventilator¹⁶⁴ and endotoxin-induced¹⁶⁵ injury, and may shift the balance from O₂-derived toward N₂-derived (i.e., nitration) reactions.^{166,167} This effect may be beneficial where greater injury is associated with oxidative versus nitration reactions.¹⁶⁸ However, it is not clear whether hypercapnic acidosis reduces in vivo tissue oxidative damage beyond its impact on neutrophils.

INNATE IMMUNE RESPONSE

Neutrophils, macrophages, and circulating monocytes are major elements in the innate immune response, and are especially important in responses to bacterial infection.¹⁶⁹ They are directly activated by bacteria, bacterial products, or inflammatory molecules such as complement. Neutrophils rapidly localize to areas of infection or inflammation, migrating from the bloodstream, and rapidly phagocytosing bacteria on contact. Phagocytosis is rapidly followed by bacterial lysis and destruction because the phagosomes fuse with toxic granules containing powerful enzymes such as elastases, proteases, nicotinamide adenine dinucleotide phosphate-oxidase (generates superoxide and hydrogen peroxide) and myeloperoxidase (generates hypochlorous acid).¹⁷⁰ Migration of PMNs is key and impairment of migration to infection sites worsens outcome in sepsis.¹⁶⁹ Circulating monocytes (and their macrophage counterparts in tissues) coordinate lymphocyte activation in sepsis by presenting bacterial antigen and secreting chemokines, and macrophages are activated by bacteria or by molecules such as endotoxin or complement components. Finally, monocytes and macrophages phagocytose and kill pathogens by similar mechanisms as—but at a slower rate than—neutrophils.

Hypercapnic acidosis inhibits neutrophil and macrophage function, and this inhibition can be sustained. For example, ex vivo inhibition of peritoneal macrophages lasts up to 3 days.^{153,156} The mechanisms are unclear but hypercapnic inhibition of macrophage TNF- α production requires

more than transient (~30 min) exposure, happens despite normal TNF- α mRNA levels, and persists long after ambient CO₂ has normalized.¹⁵⁴ Hypercapnia or acidosis may impact these processes in other ways, including alteration of intracellular pH, reduction of neutrophil recruitment or migration, inhibition of phagocyte oxidizing function, impairment of cytokine signaling among effector cells, or potentiating neutrophil death.

Phagocyte Migration, Chemotaxis, and Adhesion

Neutrophil migration is key to immune defense, and depends on processes such as cytoskeleton remodeling, membrane recycling (endocytosis, exocytosis), integrin-mediated focal adhesion attachment and reattachment, and regulation of cell volume. Many of these processes are pH dependent, and hypercapnic acidosis may therefore reduce neutrophil and macrophage recruitment to a septic focus. Acidosis impairs neutrophil chemotaxis and migration,^{171,172} and hypercapnic acidosis reduces neutrophil expression of chemokines, selectins, and intercellular adhesion molecules,^{152,157,173,174} which mediate the neutrophil-endothelial interactions required for migration out of blood vessels. Finally, hypercapnic acidosis reduces lung neutrophil migration following in vivo endotoxin.¹⁶⁵

Phagocyte Microbial Killing

Pathogens are internalized by neutrophils and macrophages within phagosomes, which merge with endosomes and lysosomes, and are lysed by powerful enzymes. This process requires bacterial phagocytosis and an intact “respiratory burst,” which produces the reactive oxygen species (O₂⁻, H₂O₂, HClO) within the endosomes and lysosomes needed for bacterial killing. Acidosis—both hypercapnic and metabolic—impairs neutrophil and macrophage phagocytosis; specifically, failure to recover intracellular pH (pHi) after acidification impedes ROS production and killing of phagocytosed bacteria in macrophages,¹⁷⁵ and metabolic¹⁷⁶ or hypercapnic¹⁷⁷ acidosis inhibits neutrophil phagocytosis. In contrast, moderate alterations of ambient pH have little effect on neutrophil phagocytosis, but markedly reduce subsequent bacterial lysis.¹⁷⁸ Finally, incubation in organic acid inhibits macrophage phagocytosis.¹⁷²

One of the enzymes largely responsible for the production of these oxygen-derived radicals, nicotinamide adenine dinucleotide phosphate-oxidase, is markedly pH sensitive.¹⁷⁹ For example, macrophage O₂⁻ production decreases linearly with reduction in pHi (below 6.8),¹⁸⁰ and hypercapnic^{152,181} and metabolic^{176,182-184} acidosis inhibits oxidant production in neutrophils that are nonstimulated^{152,181} or stimulated with a variety of chemical and microbial stimuli.^{152,184} Although marked reduction of extracellular pH to 6.5 may activate neutrophils (i.e., increasing H₂O₂ and integrin CD18) this may reflect experimental use of strong HCl.¹⁷⁴

Mechanism of Phagocyte Inhibition

Regulation of pHi is key to cell function; in general, acidosis reduces enzyme activity and protein function, particularly when pHi is less than 6.8. Because CO₂ is diffusible, hypercapnia can rapidly lower pHi and thereby inhibit neutrophil¹⁵² and macrophage¹⁸⁵ function. Two key systems regulate pHi in immune cells: the Na/H exchanger (NHE) and

the plasmalemmal V-type H ATPase.¹⁸⁶ These enzymes maintain pHi in the physiologic range (6.8 to 7.3), necessary for immune responses, as well as for other key functions including proliferation, differentiation, apoptosis, migration, cytoskeletal organization, and maintenance of cell volume.

Neutrophil pHi decreases following stimulation and activation^{152,187} and then reverts toward normal if extracellular pH is physiologic. This is important because PMNs that are unable to regulate cytosolic pH demonstrate impaired migration^{188,189} and apoptosis.^{152,190} However, extracellular hypercapnic acidosis rapidly lowers neutrophil pHi,^{152,174,188} and activated neutrophils from foci of inflammation are unable to maintain pHi following an acid challenge.¹⁹¹ Therefore persistent “acid loading,” as with ongoing permissive (or other) hypercapnia, could overwhelm the capacity of PMNs to maintain pHi and normal cell homeostasis and function. This may be especially so with PMNs that have already been activated.¹⁹¹

Neutrophil Death

Neutrophils have a short life span (<48 hours after release into the circulation) that is terminated by apoptosis, a physiologic fate following phagocyte activity. In contrast, necrosis of neutrophils after phagocytosis is a maladaptive response because microbe killing and digestion may be incomplete, and in contrast to apoptosis, enzyme release causes tissue destruction.¹⁹² Lower extracellular pH—as with hypercapnic acidosis—may delay neutrophil apoptosis and extend PMN life span.¹⁷⁴ However, hypercapnic acidosis also lowers pHi,¹⁵² which may increase neutrophil propensity to undergo necrosis rather than apoptosis.¹⁹⁰ Thus the net effect of hypercapnic acidosis on neutrophil fate—whether beneficial or deleterious—remains unclear.

ADAPTIVE IMMUNE RESPONSE

Adaptive immunity is especially important in many cancers, which characteristically involve poor vascularization, tissue hypoxia, and acidosis,¹⁹³ a setting wherein acidosis may impair host responses to tumor cells, resulting in tumor growth and metastases. However, the impact of acidosis is complex. For example, acidosis inhibits cytotoxicity of activated killer lymphocytes¹⁹⁴ and natural killer cells,¹⁹⁵ reduces lysis of tumor cells by cytotoxic T lymphocytes,¹⁹⁶ and inhibits IL-2 stimulated lymphocyte proliferation.¹⁹⁷ In contrast, IL-2 stimulated lymphocyte motility is enhanced by acidosis,^{198,199} as is the antigen presenting capacity of dendritic cells.²⁰⁰ The net effect of these contrasting actions of acidosis is unclear. However, hypercapnic acidosis does enhance murine tumor spread,²⁰¹ raising concerns about hypercapnia-induced suppression of cell-mediated immunity.¹⁵³

BACTERIAL PROLIFERATION

Hypercapnia and acidosis exert distinct effects on bacterial proliferation. For example, optimal anaerobic growth of *Escherichia coli* is seen at a PCO₂ of approximately 0.05 atmospheres (similar to the usual gut *E. coli* environment); it is not inhibited at a PCO₂ of approximately 0.2 atmo-

spheres but is inhibited at greater than 0.6 atmospheres.²⁰² Indeed, *E. coli* colony counts were halved at a CO₂ of approximately 350 atmospheres, a massive dose.²⁰³ Although the mechanisms are unclear, such inhibition is mediated directly by CO₂,²⁰⁴ and the effects are broadly similar among microbes, with yeasts being more resistant and gram-negative organisms being more susceptible.²⁰⁵

Although important, the levels of CO₂ in these studies are far higher than encountered in humans. In fact, clinically relevant levels of metabolic acidosis can enhance bacterial proliferation, as has been observed when mechanically stretched lung epithelial cells can develop lactic acidosis that augmented *E. coli* growth.²⁰⁶ Such acidosis-induced *E. coli* proliferation has been demonstrated due to H⁺-ions (not CO₂) and is abolished by local buffering.²⁰⁶

While many bacteria (*E. coli*, *Proteus mirabilis*, *Serratia rubidaea*, *Klebsiella pneumoniae*, *Enterococcus faecalis*, and *Pseudomonas aeruginosa*) isolated from patients with ventilator-associated pneumonia grew better in acidified media,²⁰⁶ at least one important pathogen (i.e., methicillin-resistant *Staphylococcus aureus*) grew optimally at alkaline pH.²⁰⁶ In summary, while bacterial growth can be inhibited by extremely high levels of CO₂, it can be enhanced by clinically relevant levels of acidosis; thus the net impact of hypercapnic acidosis on bacterial growth is a concern.

EFFECTS OF CO₂ ON REPAIR AND RESOLUTION

RESTORATION OF EPITHELIAL INTEGRITY

Elevated CO₂ directly inhibits alveolar epithelial plasma membrane resealing,²⁰⁷ and decreases repair of alveolar epithelial wounds,²⁰⁸ both important mechanisms contributing to repair following injury to the lung. Hypercapnic acidosis exerts a direct pH-dependent inhibition of lung epithelial cell membrane healing following ventilation-induced injury,²⁰⁹ a repair mechanism that depends on translocating lipids to the injured membrane.²¹⁰ In contrast, the effect of elevated CO₂ on pulmonary epithelial wound repair appears dependent on the hypercapnia rather than the acidosis per se, and appears to be mediated via effects on cell migration.²¹¹ CO₂ (pH-independent) induction of microRNA-183 (miR-183), albeit with high PCO₂ levels (120 mm Hg), may lead to mitochondrial dysfunction, which in turn impairs cell proliferation and survival.²¹²

LUNG PERMEABILITY AND FLUID CLEARANCE

Lung water accumulation and clearance are important contributors to injury and repair, respectively. Hypercapnic acidosis directly reduces,²¹³ while hypocapnic alkalosis worsens,⁷⁴ ischemia-reperfusion-induced pulmonary capillary permeability. In contrast, hypercapnia reduces alveolar fluid clearance in healthy isolated perfused lungs.⁷⁵ Hypercapnia appears to activate extracellular signal-regulated kinase,²¹⁴ which in turn activates adenosine monophosphate-activated protein kinase, leading to endocytotic withdrawal of Na⁺/K⁺-ATPase from the basolateral membrane of alveolar epithelial cells.⁷⁵

CELLULAR SENSING AND GENE ACTIVATION

MECHANISMS OF CELLULAR SENSING

As discussed in the section on regulation of arterial CO_2 , cellular sensing of CO_2 is best characterized in central and peripheral nerve cells in relation to control of breathing. However, it remains unclear whether these chemosensitive neurons detect alterations in CO_2 directly or via changes in H^+ concentrations. In addition, HCO_3^- (but not CO_2 or H^+) directly activates adenylate cyclase,²¹⁵ increasing cyclic adenosine monophosphate²¹⁶ and activating protein kinase A; this in turn results in opening of L-type Ca^{2+} channels, permitting Ca^{2+} influx.⁵ Such changes may mediate responses of putative (but as yet unidentified) CO_2 receptors. In addition, increased CO_2 (independent of pH) activates L-type calcium channels in the glomus cells of the carotid nucleus, also resulting in calcium influx.^{217,218}

GENE ACTIVATION

An important downstream consequence of cell sensing is gene activation. Key insights into CO_2 -induced gene activation have been gained by gene array studies in murine lung tissue,^{219,220} nematode (*Caenorhabditis elegans*),²²¹ and the fruit fly (*Drosophila melanogaster*)²²² following exposure to high concentrations of CO_2 .

Neonatal mice exposed to atmospheric hypercapnia demonstrated increased expression of lung genes involved in regulating cell adhesion, growth and signal transduction, and suppression of genes involved in innate immunity.²¹⁹ Hypercapnia also suppressed lipopolysaccharide-induced cytokine production (and phagocytosis) by murine macrophages, possibly explained by concomitant suppression of NF- κB ²²⁰ and consistent with impaired NF- κB signaling induced by hypercapnia in mouse embryonic fibroblasts and other mammalian cell types.²²³

CO_2 exposure also caused altered gene expression in model organisms *C. elegans*²²¹ and *D. melanogaster*,²²² where such transcription regulation has been largely attributed to inhibition of the NF- κB family of transcription factors. For example, hypercapnia-impaired innate immune responses in *D. melanogaster* increased susceptibility to bacterial infection and were associated with suppression of Relish (an NF- κB homolog) and its associated genes.²²¹

Thus CO_2 causes common gene expression patterns that are conserved across diverse species. Key features include suppression of genes associated with innate immunity and inhibition of NF- κB signaling²²⁴ (Fig. 86-4). NF- κB is sequestered in the cytosol by inhibitory molecules (I κB s), and inflammatory stimuli activate upstream signaling cascades, causing phosphorylation and degradation of I κB ; this liberates NF- κB , permitting its translocation to the nucleus where it activates expression of genes involved in innate immunity and inflammation.²²⁵ CO_2 directly inhibits the NF- κB pathway, likely through CO_2 -induced nuclear

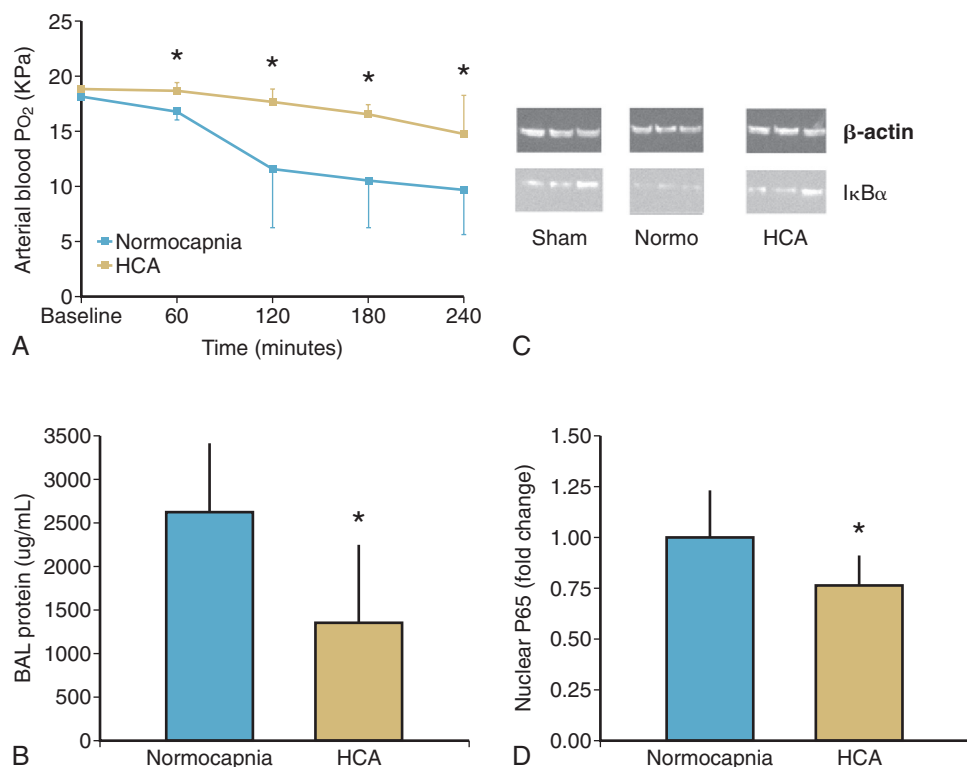

Figure 86-4 Hypercapnic acidosis (HCA) reduced high stretch ventilation-induced lung injury and indices of activation of the NF- κB pathway in the rodent. HCA reduced the decrement in arterial oxygen pressures (A) and reduced bronchoalveolar lavage (BAL) protein concentrations (B) compared to normocapnia. HCA inhibited the activation of the NF- κB pathway by excessive mechanical stretch. Specifically, HCA abolished the decrease in cytoplasmic concentrations of the NF- κB inhibitor, I $\kappa\text{B}\alpha$ concentrations (C). This results in a decreased nuclear concentration of the active P65 subunit of NF- κB , with HCA compared to normocapnia (D). *Significantly different from normocapnia ($P < 0.05$, ANOVA). (From Contreras M, Ansari B, Curley G, et al: Hypercapnic acidosis attenuates ventilation-induced lung injury by a nuclear factor-kappaB-dependent mechanism. *Crit Care Med* 40(9):2622–2630, 2012.)

localization of the IKK α subunit, thereby preventing degradation of I κ B.²²³ The protective effects of hypercapnia in mechanical stretch-induced injury in vitro and in ventilation-induced lung injury in vivo appeared to be mediated via inhibition of the NF- κ B pathway.²²⁶

PULMONARY PATHOPHYSIOLOGY

PRECLINICAL MODELS

Hypercapnic acidosis is protective in several in vivo and ex vivo lung injury models, including lung injury caused by endotoxin,¹⁶⁵ pulmonary,^{162,163} and mesenteric⁶⁶ ischemia-reperfusion, in addition to ventilator-induced lung injury^{66,164,227,224} (see Fig. 86-4). In *E. coli* pneumonia, hypercapnia attenuates histologic injury²²⁸ by a neutrophil-independent mechanism,²²⁹ and it attenuates lung injury caused by short-term and more prolonged systemic polymicrobial sepsis.²⁰⁸ In contrast to acute pulmonary hypertension, chronic exposure to hypercapnia causes reversal of hypoxia-induced pulmonary hypertension in adult²³⁰ and neonatal²³¹ rats, and protects against parenchymal and vascular injury in neonatal lungs.²³²

In contrast to protective effects, hypercapnia has several adverse effects on immunity and repair. While protective in acute²²⁹ and more established²²⁸ lung sepsis, hypercapnia over a longer period (48 hours) is associated with increased bacterial proliferation and more marked lung injury.¹⁷⁷ Furthermore, hypercapnia induced by lowered respiratory rate and tidal volume exacerbated endotoxin-induced lung injury²³³ and increased neutrophil adhesion and adhesion molecule expression.²³⁴ Finally, as discussed earlier, important aspects of injury resolution may also be impaired by hypercapnia, such as epithelial wound repair^{207,211}—likely via inhibition of NF- κ B²¹¹—and clearance of alveolar edema.⁷⁵

Hypocapnia has long been recognized as associated with adverse lung effects and was thought to be pathogenic in ARDS.²³⁵ Hypocapnia may contribute to lung injury in two ways. First, high tidal volume that induces hypocapnia can separately cause ventilator-induced lung injury.²³⁶ Second, hypocapnia may directly injure the lung in the absence of ventilator-induced injury and can increase permeability,⁷⁴ decrease compliance,²³⁷ inhibit surfactant,²³⁸ and potentiate inflammation.^{66,239,240} These effects can be ameliorated by normalizing alveolar CO₂,^{66,238,239,241} and in some cases the effects can be prevented by elevated inspired CO₂.^{66,163,165,213} Finally, alveolar hypocapnia attenuates hypoxic pulmonary vasoconstriction, worsening intrapulmonary shunt, and systemic oxygenation.⁶⁴

ACUTE RESPIRATORY DISTRESS SYNDROME

Trials of low tidal volume ventilation provide little direct insight into any independent role of CO₂ because patients have not been randomized to hypercapnia per se; in fact, in the large ARDS Network trial comparing target tidal volumes of 6 versus 12 mL/kg, there was only a mean 5 mm Hg greater arterial PCO₂ in the lower tidal volume arm.²³⁶ Nonetheless, using the database from this large trial, multivariable analysis suggested that moderate levels

of hypercapnic acidosis (pH 7.15 to 7.35; arterial PCO₂ 45 to 65 mm Hg) significantly lowered the odds ratio for death in the 12 mL/kg (but not in the 6 mL/kg) group,²⁴² suggesting that permissive hypercapnia may limit ventilator-induced lung injury. In addition, a smaller study by Amato and colleagues²⁴³ reported reduction in mortality from a combination of lower tidal volume and higher positive end-expiratory pressure (resulting in substantially greater arterial PCO₂) on survival in ARDS. This study²⁴³ and the retrospective studies on permissive hypercapnia^{19,20} demonstrate a link, but not a cause-and-effect relationship, between higher arterial PCO₂ and improved outcome.

ASTHMA

Among common causes of respiratory failure, status asthmaticus is associated with the highest levels of hypercapnia (arterial PCO₂ often greater than 100 mm Hg, pH often approaching 7)^{244,245}; this is usually transient and well tolerated, and survival is the rule. In the first substantial series of patients with severe acute asthma requiring mechanical ventilation, institution of controlled hypoventilation (i.e., permissive hypercapnia),¹⁷ complications, and mortality were considerably lower than previously reported. Although such findings have been confirmed repeatedly,²⁴⁶⁻²⁵² it is not possible to determine whether hypercapnia provided any benefit beyond minimization of barotrauma due to the lower tidal volumes.

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Hypercapnia in chronic obstructive pulmonary disease is associated with poor prognosis,²⁵³⁻²⁵⁶ although any prognostic impact of hypercapnia is confounded by the influence of other underlying factors, including alveolar loss, hypoxemia, and airway obstruction.²⁵⁷ However, in patients receiving long-term domiciliary O₂, higher arterial PCO₂ may be associated with lower mortality²⁵⁸; this would suggest a distinction between progressive hypercapnia due to terminal respiratory failure versus adaptive hypercapnia due to respiratory center recalibration and tolerance of higher arterial PCO₂, thereby lowering respiratory drive and lessening respiratory work.^{259,260} Such an “adaptive” mechanism would cause a progressive decline in arterial PO₂ due to progressively decreasing minute ventilation, but this could be addressed by supplemental oxygen therapy.

NEONATAL AND PEDIATRIC RESPIRATORY FAILURE

Hypercapnia appears to be safe and is associated with some benefits in the setting of neonatal and pediatric respiratory failure. Neonatal respiratory distress syndrome is a disorder of surfactant production in the preterm newborn and results in parenchymal stiffness and alveolar collapse. In this setting, ventilation strategies involving permissive hypercapnia (45 to 55 mm Hg) was demonstrated in a randomized clinical trial to facilitate weaning from mechanical ventilation, although there was no clear effect on chronic lung disease or survival in this small study²⁶¹ (Fig. 86-5). Data also exist supporting the use of permissive hypercapnia in other pediatric respiratory pathologies, such as

Figure 86-5 A ventilation strategy incorporating permissive hypercapnia reduced the duration of mechanical ventilation in neonates with respiratory failure compared to conventional therapy. (From Mariani G, Cifuentes J, Carlo WA: Randomized trial of permissive hypercapnia in preterm infants. *Pediatrics* 104(5 Pt 1):1082–1088, 1999.)

congenital diaphragmatic hernia, pulmonary hypertension of the newborn, and congenital heart disease.

CENTRAL NERVOUS SYSTEM PATHOPHYSIOLOGY

Hypocapnia is widely used in the management of acute brain injury, and may be lifesaving when ICP is critically elevated, but the use of hypocapnia outside this specific setting can produce neuronal ischemia and injury, resulting in harm. Hypercapnia is usually avoided in the setting of acute brain injury because it increases CBF and volume, which may cause or exacerbate intracranial hypertension. Even so, hypercapnia may have protective effects in the brain in specific circumstances.

PRECLINICAL MODELS

Hypocapnia has been demonstrated to exert potentially harmful effects in acute brain injury. Hypocapnia worsens ischemic brain injury,²⁶² diminishes neuronal energy status (i.e., glucose utilization, phosphate reserves),²⁶³ and worsens CNS functional and histologic outcomes following experimental cardiac arrest in dogs.²⁶⁴ Severe hypocapnia increases *N*-methyl-D-aspartate receptor-mediated neurotoxicity in the newborn^{265,266} and may impair neuronal membrane function through increased incorporation of choline into membrane phospholipids.²⁶⁷

Through increasing O_2 demand and decreasing supply, hypocapnia can adversely shift the global CNS O_2 supply-demand balance. Cerebral vasoconstriction may reduce overall perfusion,¹¹³ and in focal ischemia, blood flow to the hypoxic regions is selectively lowered²⁶³ and infarct size increased.^{263,268} Hypocapnia also increases CNS O_2 demand by increasing neuronal excitability,²⁶⁹ increasing excitatory synaptic transmission,²⁶⁹ and affecting the neuronal membrane itself.¹²⁰

Termination of sustained hypocapnia can precipitate cerebral hyperemia and raised ICP. During sustained hypocapnia, brain extracellular fluid becomes depleted of HCO_3^- , thereby reducing buffering capacity; thus any subsequent increase in arterial PCO_2 —because it is less buffered—will result in an exaggerated increase in CBF. This has been experimentally verified in rabbits²⁷⁰ and goats.¹¹⁶

In contrast, hypercapnia may exert direct protective effects in the injured brain. Hypercapnic acidosis decreases disruption of the blood-brain barrier in hypertensive crisis²⁷¹ and attenuates hypoxic-ischemic^{262,263} and hypoxia/reoxygenation¹⁶¹ brain injury. Hypercapnic acidosis is more effective than comparable degrees of metabolic acidosis in prevention of lipid peroxidation in cortical homogenates.²⁷²

TRAUMATIC BRAIN INJURY

Hypocapnia is commonly used in the management of patients with traumatic brain injury despite there being no evidence to show that it improves outcome. On the contrary, a randomized controlled trial of prolonged hyperventilation in traumatic brain injury demonstrated that it worsened outcome.²⁷³ Patients with severe traumatic brain injury were randomized to normal (arterial PCO_2 35 mm Hg) versus prophylactic hyperventilation (arterial PCO_2 25 mm Hg) targets; among the less severely injured patients (Glasgow Coma Scale motor score 4–5), fewer in the hyperventilation group had a favorable outcome at 3, 6, and 12 months than did those managed with normocapnia.²⁷³ Important insights were gained from this study: there was greater ICP variability and higher mean ICP levels after 60 hours of hyperventilation. Thus hyperventilation was at best ineffective in terms of its primary rationale (i.e., reduction of ICP); in fact, it worsened ICP.²⁷³ Finally, the adverse effects of hypocapnia seemed less serious in a third study group who received hyperventilation plus buffering (with tromethamine); however, these patients may have been less severely injured.

NEONATAL BRAIN INJURY

Hypocapnia (either deliberate or accidental) is common in neonatal practice. Unfortunately it appears to be particularly injurious to the premature human brain, especially in neonatal white matter injury.^{274–279} Hypocapnia is a key risk factor for several specific lesions, including periventricular leukomalacia, causing significant neonatal mortality and long-term neurodevelopmental deficits²⁸⁰; pontosubicular necrosis, a pattern of acute brain injury seen in premature infants²⁷⁷; and the pathogenesis of cerebral palsy.²⁸¹

The mechanisms predisposing premature neonates to injury from hypocapnia include vulnerable regions due to poorly developed vasculature²⁸²; reduced defenses because of antioxidant depletion by excitatory amino acids²⁸³; lipopolysaccharide²⁸⁴ and inflammatory mediators²⁸⁵ potentiating white matter destruction.

Preterm infants exposed to severe (arterial PCO_2 < 15 mm Hg) hypocapnia, even if only for a brief period, may develop considerable long-term neurologic abnormalities compared with matched, nonexposed controls.²⁸⁶ Risk factors for hypocapnia in small infants include

hyperventilation,²⁸⁶ high-frequency ventilation,¹⁶ or ECMO.¹⁴ Indeed, hypocapnia in infants prior to the initiation of ECMO is associated with an increased incidence of sensorineural hearing loss by school age.¹⁴ Finally, abrupt termination of hyperventilation results in reactive hyperemia, which may cause intracranial hemorrhage, particularly in premature infants.²⁸⁷

ACUTE STROKE

Hyperventilation has traditionally been used as a therapy in patients with acute stroke for two reasons. First, hypocapnia was thought to shunt blood preferentially to ischemic areas by selective vasoconstriction in normal autoregulated brain regions; this was called the *inverse steal* phenomenon. Second, hypocapnia was considered to correct regional acidosis adjacent to the ischemic zone, in order to minimize the extension of the infarct.²⁸⁸ However, the inverse steal phenomenon is no longer accepted²⁶⁸; in fact, hypocapnic alkalosis has been associated with poor prognosis in patients with acute cerebrovascular accidents.^{289,290} Cheyne-Stokes respiration and central sleep apnea, which can be observed after stroke, are thought to be due to decreased cerebral chemosensitivity to CO₂ in the setting of significant cerebral infarction and left ventricular systolic dysfunction.²⁹¹

NEUROPSYCHOLOGICAL IMPACT

Marked intraoperative hypocapnia—even briefly—can cause detectable neuropsychological impairment for up to 48 hours after general anesthesia²⁹²; older patients are more susceptible with greater impairment after exposure to low CO₂ levels. The impairment includes slowed reaction times,¹²⁶ as well as higher functions including attention, learning, and personality changes.^{293,294} More severe hypocapnia (arterial PCO₂ of approximately 15 mm Hg) lowers psychomotor performance in healthy volunteers²⁹⁵; in contrast, elevated arterial PCO₂ during anesthesia is associated with improved neuropsychological performance.^{292,296} Hypocapnia is also associated with adverse neurologic outcome following cardiopulmonary bypass,²⁹⁷ although in this setting there are multiple additional contributors.

Whereas adverse neuropsychological effects of transient hypocapnia appear to be reversible,^{111,292} this is not the case following prolonged exposure. Impairment following exposure at extremes of altitude can be long-standing; the deficits are better correlated with the levels of hypocapnia versus the degree of hypoxemia,²⁹⁸ consistent with the idea that individuals who can develop the lowest arterial PCO₂ levels—required to maximize alveolar O₂ content and minimize hypoxemia—are most at risk. Thus a paradox exists: climbers with greater levels of physical fitness, that is, who can develop the greatest minute ventilation, may be the most vulnerable to CNS sequelae. It is likely that profound CNS alkalosis is the basis for the deficit: intense cerebral vasoconstriction and left-shift of the hemoglobin-oxygen dissociation curve markedly diminish O₂ delivery, negating any advantage of increased oxygen loading in the lung, while alkalosis concomitantly increases neuronal cell excitability and local O₂ consumption. Such alkalosis is ameliorated by acetazolamide pretreatment.²⁹⁹ Finally, it is likely

that induced hypocapnia (e.g., with mechanical ventilation) may result in more severe CNS compromise in those with preexisting neurologic deficit.

In contrast, as discussed earlier, hypercapnia appears to speed restoration of consciousness and neurocognitive function following anesthesia.^{22,23} The deleterious effects of hypocapnia on neurocognitive function may therefore be reversed by CO₂ administration.

CEREBRAL ISCHEMIA

The impact of hypocapnia on cerebral ischemia is most apparent in neuropsychological studies^{111,292-296,298} and in studies of cerebral perfusion or oxygenation in traumatic brain injury,^{125,300,301} cardiac arrest and resuscitation,^{302,303} and neonatal brain injury^{14,274,286,304} and stroke.^{289,290}

An initial response in traumatic brain injury is reduced cerebral perfusion,³⁰⁵ which is worsened by hypocapnia,¹²⁵ and even moderate levels (<34 mm Hg) can reduce overall CBF and increase the proportion of injured brain that is inadequately perfused.³⁰⁶ This is of particular concern because regional flow deficits can be critical in common conditions including brain contusions, underlying hematomas, and diffuse injury.^{307,308} The responsiveness of the cerebral vasculature to CO₂ is increased following brain trauma,³⁰⁰ increasing the likelihood of ischemia and consistent with the worsening of outcome that is associated with prophylactic hyperventilation in such patients.²⁷³ Hypocapnia has also been shown to induce critical cerebral ischemia in pediatric traumatic brain injury.³⁰¹

Neurologic deficit is perhaps the most important complication of cardiac arrest. Following reestablishment of spontaneous circulation, the cerebral O₂ supply and demand balance is altered, with CBF at approximately 50% of normal but with cerebral O₂ consumption increased above prearrest levels.³⁰² In this setting, hypocapnia causes cerebral ischemia³⁰³ and may therefore contribute to adverse outcome.

Premature infants are especially susceptible to a variety of brain injury syndromes, and hypocapnia contributes to several of these, including periventricular leukomalacia.^{274,304} In terms of outcome, prior exposure of premature infants to hypocapnia increases the risk of neurologic deficits,²⁸⁶ including sensorineural hearing loss.¹⁴

Finally, outcome following acute stroke appears to be worsened by hypocapnia,^{289,290} which is consistent with experimental data demonstrating that hypocapnia increases the extent of ischemic injury.²⁶³

CARDIOVASCULAR PATHOPHYSIOLOGY

MYOCARDIAL ISCHEMIA

The principal cardiac impact of major alterations in arterial PCO₂ is on myocardial oxygenation. Myocardial function following recovery from ex vivo³⁰⁹ or in vivo³¹⁰ ischemia is improved in the setting of hypercapnic acidosis, with reduction in infarct size. Accordingly, endothelial function is better preserved in aortic rings that are subjected to ischemia in the setting of acidosis.³¹¹

In contrast, hypocapnia adversely alters myocardial O₂ supply and demand balance,^{312,313} increasing cardiac contractility^{314,315} and heart rate,³¹⁶ and by increasing systemic vascular resistance, increases left ventricular work.³¹⁷ Because these parameters are key determinants of myocardial O₂ consumption, O₂ demand is precipitously increased.^{140,312,315,318,319} Compounding this, hypocapnia restricts myocardial O₂ supply. Because heart rate is increased and diastolic duration is lessened, perfusion is reduced.^{141,312,313,320-323} In addition, the hemoglobin-oxygen dissociation curve is shifted leftward, increasing the avidity of Hb for O₂. Oxygen delivery is further compromised because alkalosis results in greater capillary permeability,³²² increasing the propensity to local edema. These features explain the observation that experimental hypocapnia is associated with increased coronary arteriovenous oxygen difference and decreased coronary flow.¹⁴¹

Hypocapnia may precipitate coronary artery spasm, resulting in variant angina that may be seen in the context of hyperventilation.³¹³ Finally, hypocapnia may augment propensity to thrombosis because it can increase platelet levels and aggregation.³²⁴

CARDIAC RHYTHM DISORDERS

Both hypocapnia and hypercapnia may cause cardiac rhythm disorders. Hypocapnia is associated with dysrhythmias in the acutely ill³²⁵; it can cause paroxysmal atrial arrhythmia³²⁶ and, rarely, ventricular tachycardia³²⁷ or fibrillation.³²⁸ Such effects may be mediated by development of myocardial ischemia, especially in variant angina.³²⁷ Conversely, alkalosis may suppress arrhythmias caused by local anesthetic³²⁹ or tricyclic antidepressant³³⁰ toxicity. Hypercapnia may also cause tachyarrhythmias via activation of the sympathetic nervous system.³³¹ Restoration of normocapnia following hypercapnia has been demonstrated to increase the risk for atrial fibrillation in preclinical models.³³²

SYSTEMIC OXYGENATION

In experimental sepsis, hypercapnic acidosis improved tissue oxygenation analogous to dobutamine administration.³³³ In addition, hypercapnia may increase peripheral tissue oxygenation in healthy surgical patients independently of its effects on cardiac output.^{334,335} It appears that augmentation of tissue perfusion and oxygenation may be maximal at arterial PCO₂ levels of 150 mm Hg.¹⁴⁵

CLINICAL EVIDENCE

Arterial blood gas management during cardiopulmonary bypass can be managed using so-called pH-stat (more CO₂ is added to maintain arterial PCO₂ during temperature correction) or α -stat (no additional CO₂ added). In a randomized controlled trial involving children undergoing cardiopulmonary bypass for repair of congenital heart lesions, the pH-stat strategy was associated with better postoperative cardiac and neurologic function,³³⁶ suggesting a net benefit associated with additional perioperative CO₂ exposure.

INFECTION AND SEPSIS

EXPERIMENTAL PNEUMONIA

Adding CO₂ to the inspired gas (vs. normocapnia) resulted in less severe lung injury in an experimental model of early *E. coli* instillation²²⁹ in the rat; protective effects were observed in severe²²⁹—and not in mild³³—disease. In addition, protection was not mediated by altered neutrophil function,²²⁹ and in vivo bacterial proliferation was unchanged.^{229,337} These effects were confirmed in more established *E. coli* pneumonia (about 6 hours), in the presence or absence of appropriate antibiotics, although protection was enhanced with antibiotic therapy.²²⁸

In contrast to short-term lung infection, hypercapnia (raising atmospheric CO₂ levels) worsened lung injury during longer term established *E. coli* pneumonia in the rat.¹⁷⁷ In this setting, hypercapnia (vs. no added CO₂) was associated with lower compliance, increased PMN infiltration, and increased bacterial load. The likely mechanism for increased bacterial numbers was inhibition of neutrophil function, because PNMs obtained from the hypercapnic animals demonstrated impaired phagocytosis.¹⁷⁷ These findings have subsequently been confirmed in a murine model of established *Pseudomonas* pneumonia,³³⁸ wherein survival was also worsened. Importantly, appropriate antibiotic therapy negated the harmful effects of hypercapnia (i.e., lung injury, bacterial proliferation) in prolonged *E. coli* pneumonia.¹⁷⁷

EXPERIMENTAL SEPSIS

In a rodent model of early systemic sepsis induced by fecal peritonitis (i.e., cecal ligation and puncture), hypercapnic acidosis reduced the severity of shock as well as the extent of lung injury.²⁰⁸ The mechanisms of protection are unclear and it is unknown whether the effects on systemic hemodynamics (preservation of mixed venous SO₂, systemic perfusion pressure, serum lactate level) were independent of the pulmonary impact (i.e., better oxygenation, less edema, reduced bronchoalveolar lavage mediator levels and neutrophil count), because peritoneal and bloodstream bacterial loads were similar with and without hypercapnia exposure.²⁰⁸ In addition, survival was unaltered.

Similar effects were reported in a sheep model of established fecal peritonitis³³³ (Fig. 86-6). In this study, animals were randomized to hypercapnic acidosis, dobutamine infusion, or control conditions after development of peritonitis. Key hemodynamic parameters (i.e., heart rate, cardiac index, and oxygen delivery) were similar after randomization to hypercapnia versus dobutamine (both greater than controls), and lactate levels were lower than in normocapnic controls. However, hypercapnia—but not dobutamine—reduced indices of lung injury (e.g., lung water accumulation, shunt fraction, and oxygenation).³³³ There was no impact of hypercapnia on survival.

Intraperitoneal CO₂ is extensively used during laparoscopic surgery and results in very high levels of CO₂ in the peritoneal cavity and in the plasma. CO₂ pneumoperitoneum (vs. helium insufflation) improved survival when administered before³³⁹ or during³⁴⁰ experimental endotoxin sepsis; these findings were replicated in experimental

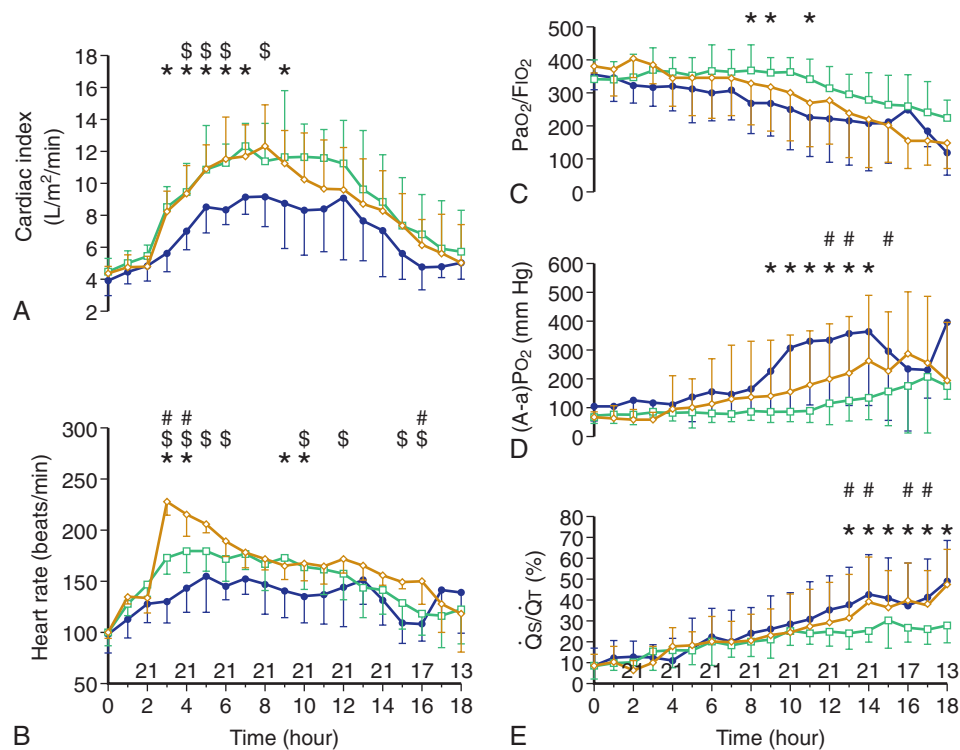

Figure 86-6 Hypercapnic acidosis improves hemodynamic function and decreases lung injury following systemic sepsis in an ovine model. Hypercapnia (green line) increased cardiac index (A) and heart rate (B) over time compared to the normocapnic animals (blue line), to an extent comparable to normocapnic animals treated with dobutamine (brown line). Hypercapnic acidosis (green line) increased the arterial PO₂/FiO₂ ratio (C), decreased the alveolar-to-arterial oxygen tension difference ((A-a)PO₂) (D), and decreased the shunt fraction (Q_s/Q_T) (E) over time compared to normocapnia (blue line) and to animals treated with dobutamine (brown line). *, *P* < 0.05 hypercapnia versus control; #, *P* < 0.05 hypercapnia versus dobutamine; \$, *P* < 0.05 dobutamine versus control. The numbers above the abscissa indicate the numbers of surviving animals at the corresponding time point. (Modified from Wang Z, Su F, Bruhn A, et al: Acute hypercapnia improves indices of tissue oxygenation more than dobutamine in septic shock. *Am J Respir Crit Care Med* 177:178–183, 2008. Figs 2 and 3.)

polymicrobial peritonitis in mouse³⁴¹ and rabbit³⁴² models (Fig. 86-7). Such protection seems to be due to immunomodulatory effects of hypercapnia³⁴³ (e.g., IL-10 mediated down-regulation of TNF- α) in conjunction with localized peritoneal acidosis—and not via a systemic effect.^{344,345}

APPROACHES TO MINIMIZE HYPERCAPNIA

Hypercapnia remains a cardinal sign of ventilatory failure and, as such, has traditionally been avoided. Advances in current understanding of the deleterious effects of excessive mechanical lung stretch in the setting of severe respiratory failure have prompted clinicians to be more tolerant of hypercapnia. Indeed, a body of literature exists that demonstrates full recovery following exposure to extreme levels of hypercapnia—termed *supercarbia*—in both adults and children. Full recovery without sequelae has been reported in several children exposed to extremes of arterial PCO₂ (155 to 269 mm Hg)³⁴⁶ and there are reports of arterial PCO₂ tensions up to 375 mm Hg (pH 6.6) in adults^{347,348} who survived without demonstrable deficits. Nevertheless, severe hypercapnia may be problematic, depressing cardiac function and potentially worsening pulmonary hypertension, particularly if rapidly accumulated.³⁴⁹ Clinicians must be mindful of the tradeoff between the beneficial and

Figure 86-7 Insufflation of CO₂ into the peritoneal cavity improves survival following cecal ligation and puncture-induced systemic sepsis. Animals were first subjected to cecal ligation and puncture. Four hours later, animals underwent a laparotomy and induction of a CO₂ pneumoperitoneum (laparotomy + CO₂), laparotomy alone or no laparotomy, and survival was determined over the following 8 days. (Modified from Metzelder M, Kuebler JF, Shimotakahara A, et al: CO₂ pneumoperitoneum increases survival in mice with polymicrobial peritonitis. *Eur J Pediatr Surg* 18:171–175, 2008. Fig 3b.)

deleterious effects of hypercapnia, and tailor treatment in each individual case. For example, in the case of combined lung and head injury, regional monitors of cerebral oxygenation and ICP may be used to guide therapy.

STRATEGIES TO REDUCE DEAD SPACE

These approaches aim to minimize any contribution of circuit and anatomic dead space to hypercapnia. At the end of expiration, the ventilator circuit distal to the Y-piece and the anatomic dead space both contain CO₂-rich alveolar gas, which is then delivered back to the distal lung with the next inspiration. The significance of this *rebreathing* is enhanced with low tidal volume ventilation strategies, because the anatomic dead space is relatively fixed. Techniques that aim to replace dead space gas with fresh gas have therefore been advocated as an adjunct to protective ventilator strategies. These techniques can increase effective alveolar ventilation, which could facilitate further reductions in tidal volume and enhance any protective effect.

Tracheal gas insufflation (TGI) delivers fresh gas into the central airways either continuously or in a phasic fashion during expiration. Preclinical studies in ARDS models demonstrate promise,³⁵⁰ with evidence to suggest that TGI may attenuate the development of ventilation-induced lung injury in surfactant-depleted lungs.³⁵¹ TGI has been demonstrated to augment CO₂ clearance when combined with high-frequency oscillation.³⁵² However, some concerns persist with regard to the safety and monitoring of TGI that continue to impede its introduction into clinical practice.³⁵³ Aspiration of dead space gas during expiration and controlled replacement with fresh gas is a related technique. A feasibility study of eight patients with chronic obstructive pulmonary disease who were managed with permissive hypercapnia demonstrated that aspiration of dead space gas resulted in a similar decrease in arterial PCO₂ but with less intrinsic positive end-expiratory pressure compared with TGI.³⁵⁴ Lastly, coaxial double-lumen endotracheal tubes, which eliminate the contribution to dead space from the ventilator circuit distal to the Y-piece, may improve the efficiency of ventilation.³⁵⁵

HIGH-FREQUENCY OSCILLATORY VENTILATION

High-frequency oscillatory ventilation (HFOV) is a nonconventional mode of ventilation in which breathing frequencies from 60 to 2400 breaths per minute (conventionally measured in hertz, with 1 hertz = 60 breaths per minute) with tidal volumes that are lower than the dead space volume (i.e., 35 to 150 mL) are used. The lung is exposed to a continuous positive pressure, and an “oscillatory” tidal volume is superimposed. Since the tidal volume is usually less than the anatomic dead space, gas exchange cannot be explained in terms of simple convective bulk transport to the alveoli. Whereas HFOV is generally used for patients with severe hypoxemia, it can be used to manage hypercarbia, especially in neonates and children.³⁵⁶ HFOV has been successfully applied to neonates since 1981,³⁵⁷ and more recently to adolescents and adults.³⁵⁸ HFOV results in better pulmonary outcomes than conventional mechanical ventilation for very-low-birth-weight infants suffering with respiratory

distress syndrome.³⁵⁹ In adults suffering from ARDS, while an earlier multicenter trial by Derdak and colleagues³⁶⁰ demonstrated promise, more recent large-scale multicenter trials have cast significant doubt on the role of HFOV in the management of ARDS.^{361,362}

EXTRACORPOREAL TECHNOLOGIES

Extracorporeal CO₂ removal (ECCO₂R) refers to the process by which an extracorporeal circuit is used for the primary purpose of removing CO₂ from the body, thereby providing partial respiratory support (see Chapter 103). ECCO₂R systems can be *arteriovenous* (AV) or *venovenous* (VV). AV-ECCO₂R systems involve the insertion of a gas exchange membrane across an AV shunt, usually created between the femoral artery and the contralateral femoral vein using percutaneously inserted cannulas. The gas exchange membrane is connected to oxygen, which acts as a “sweep gas” to remove CO₂ that has diffused out of the patient’s blood.

Theoretically, an ultra-efficient ECCO₂R system could eliminate all the CO₂ that the body produces with flow rates of just 0.5 L/min, because a liter of blood with an arterial PCO₂ of 35 mm Hg contains around 500 mL of CO₂ and the body produces approximately 250 mL/min. The potential for ECCO₂R systems to oxygenate blood is much more limited because there is effectively a limit to the amount of oxygen a given volume of blood can carry, and the extracorporeal flow rate would have to be much higher to meet the demand for O₂. By removing CO₂, ECCO₂R allows ventilation strategies that are focused on oxygenation rather than CO₂ elimination.

Until recently, the primary use of ECCO₂R has been in cases of severe hypercapnic acidosis that are refractory to mechanical ventilation. In the vast majority of cases, this has been in the context of ARDS.^{363,364} There are a number of reports of its use in other clinical scenarios, namely, as a bridge to transplant,^{365,366} in combined head and chest injury,^{367,368} in near fatal asthma,^{369,370} as an aid to weaning from mechanical ventilation,³⁷¹ to facilitate thoracic surgery,^{372,373} and to facilitate transfer.^{374,375} None of these case reports or very small case series provide any definitive evidence of benefit.

The focus of ECCO₂R is now to allow protective ventilation in patients with ARDS in whom hypercapnic acidosis has not yet become refractory; this is likely to be where its role lies in the future. Sometimes the severity of lung injury makes it impossible to stay within the low tidal volume limits of the ARDSNet ventilation strategy and ECCO₂R may have a role in facilitating protective ventilation in these situations. Furthermore, ECCO₂R could be used to reduce the tidal volume to less than 6 mL/kg when the plateau pressure is already less than 30 cm H₂O (“ultra-protective” ventilation).^{375a} Whether or not there is any benefit to ultra-protective ventilation is debatable. Indeed, the initial clinical trial of low-frequency positive pressure ventilation ECCO₂R showed promise,³⁷⁶ but a subsequent randomized controlled trial failed to demonstrate a survival benefit.³⁷⁷

Terragni and colleagues³⁷⁸ used VV-ECCO₂R to facilitate ultra-protective ventilation. They recruited 32 patients with early (<72 hr) ARDS and ventilated them according to the ARDSNet protocol for 72 hours, at which point the tidal volume was reduced from 6 to 4 mL/kg in all patients

($n = 10$) who had a plateau pressure of between 28 and 30 cm H₂O and VV-ECCO₂R commenced. This technique successfully treated the hypercapnic acidosis in all cases and allowed the protective ventilation strategy (4 mL/kg tidal volumes and higher levels of positive end-expiratory pressure) to continue. The study also demonstrated a reduction in bronchoalveolar inflammatory cytokines after 72 hours of ventilation with 4 mL/kg but not 6 mL/kg. More recently, Bein and colleagues³⁷⁹ demonstrated similar outcomes in a larger study of patients with established ARDS randomized to either the ARDSNet ventilation approach or to lower tidal and minute ventilation combined with ECCO₂R. Taken together, these studies, while relatively small, suggest that there may be benefit to an ultra-protective ventilation strategy facilitated by VV-ECCO₂R in patients with ARDS.

Overall, there is good evidence that ECCO₂R can effectively reduce arterial PCO₂ and make a small contribution to oxygenation in patients with ARDS. Perhaps more importantly, studies^{363,371,372,379} have demonstrated that ECCO₂R facilitates a lung-protective ventilation strategy by allowing a reduction in tidal volumes and inspiratory airway pressures. However, it is not possible at this stage to draw any valid conclusions about the effect of ECCO₂R on survival in patients with ARDS. Furthermore, the threshold at which a hypercapnic acidosis requires treatment is unclear and may vary depending on the clinical situation

BUFFERING A HYPERCAPNIC ACIDOSIS

One approach to the management of hypercapnia is to buffer the resultant acidosis. This remains a common—if controversial—practice in the management of patients with severe respiratory failure with protective ventilation strategies. However, there is no evidence to support buffering, and indeed, there are a number of specific concerns regarding this practice. In particular, concerns exist regarding sodium bicarbonate, the buffer used most frequently in the clinical setting. The effectiveness of bicarbonate infusion as a buffer is dependent on the ability to excrete CO₂, rendering it less effective in buffering hypercapnic acidosis. In fact, bicarbonate may further raise arterial PCO₂ where alveolar ventilation is limited, such as in ARDS. While bicarbonate may correct arterial pH, it may worsen an intracellular acidosis because the CO₂ produced when bicarbonate reacts with metabolic acids diffuses readily across cell membranes, whereas bicarbonate cannot. However, where buffering is considered in the setting of hypercapnia, there may be a role for the amino alcohol tromethamine (*tris-hydroxymethyl aminomethane*, THAM). THAM penetrates cells easily and can buffer pH changes and simultaneously reduce arterial PCO₂.³⁸⁰ Unlike bicarbonate, which requires an open system for CO₂ elimination in order to exert its buffering effect, THAM is effective in a closed or semiclosed system. THAM rapidly restores pH and acid-base regulation in acidemia caused by CO₂ retention.³⁸⁰ In ARDS patients, THAM has been demonstrated to attenuate the hemodynamic consequences of a rapidly induced hypercapnic acidosis.³⁴⁹ Therefore, if a clinician elects to buffer a hypercapnic acidosis, the rationale for this practice should be clear (e.g., to ameliorate potentially deleterious hemodynamic consequences of acidosis), and THAM should be considered rather than bicarbonate.

Key Points

- Advances in current understanding of the deleterious effects of excessive mechanical lung stretch have prompted clinicians to use ventilation strategies that result in hypercapnia. Consequently, hypercapnia has become increasingly prevalent in the critically ill.
- Both hypercapnia and hypocapnia exert potent physiologic effects: hypercapnia enhances hypoxic pulmonary vasoconstriction, ventilation/perfusion matching, cardiac output, and systemic and tissue oxygenation, and increases cerebral blood flow and volume, while hypocapnia generally has opposite effects.
- Hypocapnia remains a common—and generally underappreciated—component of many disease states, including early asthma, high altitude pulmonary edema, and acute lung injury. Induction of hypocapnia remains a common, if controversial, practice in both adults and children with acute brain injury.
- Both hypocapnia and hypercapnia can be harnessed to produce benefit, or can result in harm.
- The timing and duration of application of alterations in CO₂ tension are critically important. Based on current evidence, hypocapnia should be avoided in the setting of acute brain injury except where *intracranial pressure* (ICP) is critically elevated and, when induced, should be for a short period, while definitive measures are undertaken.
- Initial benefits of short-term application of hypocapnia or hypercapnia may be offset when the altered CO₂ state is allowed to persist, such as in hypocapnia for raised ICP, where the ICP lowering effects are gradually lost with cerebrospinal fluid buffering over several hours, and the ICP may rebound upon restoration of normocapnia.
- The effect of altered CO₂ tension depends on the specific mechanism of injury, for example, in preclinical studies, hypercapnic acidosis is beneficial in early sepsis, via inhibitory effects on the host immune response. However, hypercapnia worsens prolonged untreated pneumonia because an intact host immune response is central to effective bacterial clearance.

Mechanisms

INTRODUCTION

Disturbed sleep is increasingly being recognized as a major contributor to various deleterious health outcomes. Sleep deprivation is well known to impair cognition, mood, and memory, but more recent evidence indicates that sleep deprivation also has a major impact on cardiometabolic function. *Obstructive sleep apnea* (OSA), a common condition with well-established neurocognitive and cardiovascular sequelae, is covered elsewhere in this book (Chapter 88). Other causes of sleep fragmentation such as central sleep apnea (Chapter 89), periodic limb movements, and hypoventilation syndromes (Chapter 85) are also being studied. The term *sleep disruption* is often used in a general sense to refer to conditions of sleep fragmentation (such as OSA) and sleep deprivation (in which total sleep time is reduced).

SHORT-TERM CONSEQUENCES WITH POTENTIAL LONG-TERM SEQUELAE

NEUROCOGNITIVE CHANGES

Sleep disruption is associated with major neurocognitive changes that can affect performance in the short term and may impact long-term cognitive function. The cognitive dysfunction associated with sleep restriction for 28 hours has been shown to be roughly equivalent to that associated with consuming alcohol up to a blood alcohol level of 0.10%, which is above the legal driving limit in most states.¹ Studies of partial and total sleep deprivation indicate a decline in many separate measures of broad cognitive performance, including slowed response time, decrease in short-term and working memory, reduced learning of cognitive tasks, and decreased situational awareness.² Sleep deprivation decreases related executive function (via the pre-frontal cortex), which is responsible for working memory.³ For the individual who has been sleep deprived, this influence may result in decreased insight into the scope of a problem, decreased flexibility in thinking, a propensity for perseveration, and difficulty assimilating and integrating new information, as well as understanding the temporal order of information.^{3,4} Similarly, studies of cognitive function in patients with *sleep disordered breathing* (SDB) indicate that, compared with the general population, sleep apnea

patients exhibit moderate to severe defects in sustained attention tasks (such as the psychomotor vigilance task), driving simulation, and working memory tasks requiring flexibility and insight in thought.⁵ SDB patients also demonstrate moderate deficits in verbal fluency, short attention tasks, decreased vigilance, and decreased intellectual function.⁶

More recently, functional magnetic resonance imaging and positron emission tomography studies have been employed to evaluate the cognitive effects of sleep deprivation and fragmentation by evaluating metabolic fluctuations in glucose uptake in specific brain regions. Some data indicate that sleep deprivation results first in global decreases in cortical and subcortical structures.⁷ As people become cognitively impaired, metabolism decreases more specifically in the prefrontal cortex, thalamus, and posterior association cortices, which are believed to be responsible for supporting attention.⁷ At 24 hours of sleep deprivation, the thalamus is activated when given an attention-demanding task, which has been characterized as the need for increased “mental energy” to maintain attention during sleep deprivation.⁸ When given a verbal working memory task after 35 hours of sleep deprivation, increased parietal lobe activity is noted, which may be a compensatory mechanism to help improve overall declining working memory.⁹ Further studies are necessary to elucidate better the mechanisms of cognitive dysfunction associated with sleep deprivation.

SLEEP AND IMMUNE FUNCTION

Disrupted and restricted sleep has also been implicated in proper functioning of the immune system. A prospective study by Patel and colleagues¹⁰ assessing nearly 57,000 female nurses (ages 37 to 57 years) found that both short and long sleep duration predicted increased risk of community-acquired pneumonia. Compared with those who slept for 8 hours, women who slept less than 5 hours had a relative risk of 1.4 (CI 1.1 to 1.8) of developing pneumonia. Women who slept more than 9 hours had a similar increased risk for developing pneumonia. A correlation was also found between perceived sleep quality and increased pneumonia risk.¹⁰ Another study evaluated 153 healthy volunteers (both men and women) and found that those who reported sleep of less than 7 hours were 2.9 times (95% CI 1.2 to 7.3) more likely to develop symptoms of a common cold following study-administered intranasal

exposure to rhinovirus.¹¹ Studies to elucidate the mechanism of impaired immunity have found that sleep-deprived humans have lower *natural killer* (NK) cell activity and IL-2 production, along with increased production of inflammatory biomarkers.¹² In animals, chronic sleep deprivation has been found to reduce monocyte numbers, complement C3 levels, and spleen weight. Furthermore, studies of sleep-deprived animals have shown increased rates of bacteremia.¹³

Along these lines, studies in healthy mice have shown that sleep deprivation ablates the response to influenza vaccination to such an extent that the sleep-deprived mice appeared to have no development of immunity after receiving the vaccine.¹⁴ A study of hepatitis B vaccination titers in humans showed that short sleep duration (as evaluated by actigraphy, i.e., activity monitors, and sleep journals) was associated with a lower secondary antibody response to the vaccine.¹⁵ Similarly, another study showed that one period of 24-hour sleep deprivation significantly reduced H1N1 antibody titers at 5 days postimmunization in healthy volunteers.¹⁶ This effect, however, was not prolonged because total antibody titers were not significantly different at 10, 17, and 52 days postimmunization. This study had a small sample size ($n = 24$) and larger studies are necessary. The impact of sleep deprivation on immunity and vaccine titers is particularly relevant in critically ill patients in which iatrogenic infections may have devastating consequences. Further studies will need to quantify and mitigate the risk associated with sleep deprivation and infections in *intensive care unit* (ICU) patients.

SLEEP AND THE INTENSIVE CARE UNIT

Besides effects on immunity, sleep deprivation has other important implications for ICU patients.²⁴ The ICU setting leads to sleep disruption due to excessive environmental stimuli such as alarms, noise from health care providers and other patients, as well as routine interruptions for patient care. Sleep disruption has been hypothesized to contribute to delirium, impaired immune function, and prolongation of mechanical ventilation in critically ill patients. Delirium has been associated with prolonged ICU stays, as well as increased ICU mortality.

The relationship between disrupted sleep and delirium is controversial in part due to the difficulty in distinguishing cause and effect. Key features of delirium are also seen in sleep-disrupted patients, including inattention, fluctuating mental status, and cognitive dysfunction. A study by Trompeo and colleagues¹⁷ of mechanically ventilated patients examined the relationship of ICU delirium with sleep patterns. The authors prospectively followed intubated patients until their sedation had been discontinued for more than 24 hours and the patients were alert, cooperative, and ready to wean from the ventilator. At this point, they measured nocturnal *polysomnograms* (PSGs) on each patient for one night. Among patients with severe *rapid eye movement* (REM) sleep reduction ($<6\%$ REM), 73% had delirium.¹⁷ Among the patients with more than 6% REM sleep, only 9% had delirium. Although interesting, this study does not address whether the primary event was sleep deprivation or delirium. Further studies will be necessary to determine the mechanisms by which sleep disruption

impacts delirium, as well as the potential impact of various interventions on clinical outcomes.

A study by Rompaey and colleagues¹⁸ randomized adult ICU patients to earplugs at bedtime (during the night shift) versus no earplugs and assessed self-reported sleep perception and delirium on the basis of the NEECHAM scale (a standardized test for confusion based on neurocognitive processing, behavior, and physiologic control). They found that the patients using earplugs had better perceived sleep, a lower incidence of confusion, and delayed onset of confusion.¹⁸ No difference was noted in the rate of delirium, a finding that is not surprising because it is unlikely that one intervention would eliminate delirium given the multifactorial nature of this syndrome. This study was encouraging in that it showed that a simple, inexpensive intervention may be beneficial as an adjunct to caring for the critically ill.

Ventilator dyssynchrony is also a likely culprit causing sleep disruption in the ICU. In one study in critically ill mechanically ventilated patients, better synchrony with the use of proportional assist ventilation versus standard pressure support ventilation improved sleep quality.¹⁹ Another study demonstrated that air leak during noninvasive ventilation was associated with disrupted sleep. This finding may be related to a disruption in respiratory pattern versus orofacial mechanoreceptors.²⁰

Currently, it is unclear what the implications of sleep loss are on pulmonary mechanics and ventilator weaning in ICU patients. A study in healthy men who were sleep deprived for 30 hours revealed a decrease in inspiratory muscle endurance and maximum voluntary ventilation.²¹ Sleep deprivation was initially thought to reduce chemoreceptor-mediated hypercapnic ventilator drive, but a more recent study by Spengler and colleagues²² showed that 24 hours of sleep deprivation did not affect the sensitivity of central chemoreceptors during resting ventilation. In critically ill tracheostomized patients undergoing a prolonged weaning from ventilation, sleep quality was similar whether on a ventilator or not overnight, but sleep quantity was greater on the ventilator; the authors recommended that patients in prolonged weaning will have greater sleep efficiency if ventilated at night.²³ Further research is necessary to understand the implications of sleep deprivation on weaning from mechanical ventilation.

Poor sleep has been reported in up to 61% of critical care survivors. The impact of this finding is unclear, but poor sleep may contribute to depression, post-traumatic stress disorder, and possibly impaired exercise tolerance among ICU survivors.^{25,26}

EFFECT ON CHRONIC DISEASE STATES

METABOLIC

Basic science, translational, and epidemiologic studies indicate that diminished and disrupted sleep predisposes an individual to both obesity and diabetes via altered glucose metabolism, insulin resistance, and dysregulation of appetite control via the neuroendocrine system. Many studies

have found a higher prevalence of diabetes within the OSA population with odds ratios from 1.4 to 2.2.²⁷⁻²⁹ Furthermore, restricted and disrupted sleep has been shown to predict glucose control in type 2 diabetes. A study by Aronsohn and colleagues³⁰ performed an in-laboratory PSG and measured HbA1c in 60 diabetic patients. They found that compared with patients without OSA, the adjusted mean HbA1c was increased by 1.5% in patients with mild OSA, 1.9% in patients with moderate OSA, and 3.7% in patients with severe OSA.³⁰

An initial sleep debt study looked at healthy male volunteers and subjected them to 4 hours of sleep nightly for 6 days followed by 7 nights of 12 hours in bed. The subjects underwent IV glucose tolerance tests on days 5 and 6 and after 7 nights of rest. They found that the acute response to insulin was diminished by 30% in the sleep-restricted compared with the well-rested state. Furthermore, their disposition index (a product of the acute response to insulin and insulin sensitivity) was 40% lower during sleep restriction.³¹ A low disposition index indicates a higher risk of type II diabetes, and these patients in fact had disposition indices in the range similar to those reported in epidemiologic studies of patients at higher risk for type II diabetes (i.e., Hispanic women with prior gestational diabetes). A proposed mechanism for this finding may be via sympathoexcitation and release of counter-regulatory hormones associated with sleep disruption.³²

CARDIOVASCULAR DISEASE

Multiple studies have documented a relationship between clinical cardiovascular disease and sleep disruption. A large, prospective 10-year cohort study followed more than 70,000 U.S. female health care workers with no known heart disease at baseline to evaluate the incidence of coronary heart disease and its relationship to self-reported daily sleep duration. Fascinatingly, this study showed that short sleep and long sleep were independently associated with a modest increase in incidence of coronary heart disease. This finding mimics the bimodal distribution seen in studies of sleep deprivation and immune dysfunction. The age-adjusted relative risks for individuals reporting fewer than 5 hours per night, 6 hours per night, 7 hours per night, and 9 hours per night were 1.8 (1.3 to 2.4), 1.3 (1.1 to 1.6), 1.1 (0.9 to 1.3), and 1.6 (1.2 to 2.1), respectively.³³

A similar study of more than 98,000 Japanese men (42%) and women (58%) aged 40 to 79 years investigated cardiovascular mortality in relation to self-reported sleep duration. The study group had a median follow-up of 14.3 years from 1988 to 1990 through 2003. Compared with a sleep duration of 7 hours, a sleep duration of 4 hours was associated with increased mortality from cardiovascular disease in women (hazard ratio of 2.3), as well as an increase in mortality from all causes among both men and women (hazard ratios of 1.3 for men and 1.3 for women).³⁴ Interestingly, an association was not seen for reduced sleep and cardiovascular mortality in men. Another study examined the relationship between short sleep duration and incident coronary calcification in healthy middle-aged adults. Computed tomography performed in 2000-2001 and 2005-2006 in the cohort revealed that longer sleep duration was associated with a reduced incidence of coronary artery

calcification with an adjusted odds ratio of 0.7 per extra hour of sleep.³⁵ This conclusion was made after accounting for potential confounders (age, sex, race, education, apnea risk, smoking status) and mediators (lipids, blood pressure, body mass index, diabetes, inflammatory markers, alcohol consumption, depression, hostility, self-reported medical conditions). Thus considerable epidemiologic data support a strong association between reduced sleep duration and coronary disease.

Disrupted sleep has a role in the pathogenesis of hypertension, perhaps secondary to disrupted balance of sympathovagal tone. Prospective studies have demonstrated that nocturnal blood pressure is a better predictor of cardiac risk than daytime blood pressure.^{36,37} One prospective study evaluated cardiovascular outcomes for more than 5000 patients with hypertension over a median period of 8.4 years and found that nocturnal blood pressure was the strongest predictor of cardiovascular mortality and that an increase of 10 mm Hg in mean nocturnal blood pressure corresponded with a 21% increase in cardiovascular mortality.³⁶ Another prospective study evaluated the effect of 24 hours' sleep deprivation on systolic and diastolic blood pressure in 8 healthy normotensive young adults (mean age 24) versus 8 healthy normotensive older adults (mean age 64) and found a significant increase in both diastolic and systolic blood pressure in the elderly group.³⁸ OSA has a significant correlation with both systemic and pulmonary arterial hypertension. There is strong evidence from animal studies that OSA contributes to systemic hypertension through mechanisms of intermittent hypoxia, sympathetic activation, and alterations in the renin-angiotensin system.

Disrupted sleep has also been shown to predict arrhythmias. OSA has been documented to have an association with atrial fibrillation, nonsustained ventricular tachycardia, and complex ventricular ectopy.³⁹ Even in healthy young adults without OSA, a single night of sleep deprivation has been associated with increased atrial electromechanical delay, a marker of risk for various arrhythmias such as atrial fibrillation.⁴⁰

MECHANISMS

The pathophysiologic consequences of sleep disruption are related to multiple alterations that take place following attenuated or disrupted sleep, including low-grade systemic inflammation, increased oxidative stress, dysautonomia, and endothelial dysfunction (Fig. 87-1).

Systemic Inflammation

Both total sleep loss and even modest sleep reduction (to 6 hours/night) are known to be associated with an increase in secretion of the proinflammatory cytokines IL-6 and *tumor necrosis factor* (TNF)- α .⁴¹ Though the biologic consequences of these increases have been relatively underexplored, elevations of IL-6 and TNF- α have been noted in disease states associated with systemic inflammation including insulin resistance and cardiovascular disease.⁴² Development and rupture of the vascular atherosclerotic plaque is a complex inflammatory-modulated cascade of events⁴³ involving cytokine-mediated recruitment and adhesion of T cells and monocytes to the vascular wall. Both IL-6 and TNF- α are synthesized and secreted by white

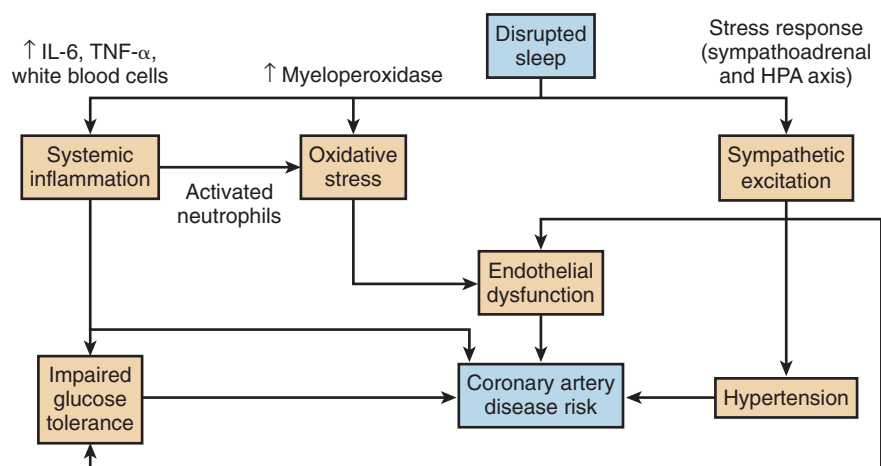

Figure 87-1 Proposed mechanisms by which sleep disruption increases the risk for coronary artery disease. Disrupted sleep may act by several mechanisms to increase coronary artery disease, mainly by effects on systemic inflammation, oxidative stress, and sympathetic excitation. The challenge in studying the role of sleep is in isolating particular mechanisms when they are closely inter-related. HPA, hypothalamic-pituitary-adrenal.

blood cells, endothelial cells, and adipocytes.⁴⁴ C-reactive protein, an acute-phase reactant and a well-established clinical indicator of systemic inflammation, is synthesized in the liver predominantly by IL-6 activation.^{45,45a} Multiple experimental studies (both animal and human) have shown elevations of IL-6, TNF- α , white blood cell count, and C-reactive protein in both acute and long-term partial and total sleep deprivation. Furthermore, patients reporting chronically shortened or disrupted sleep have been shown to have elevated levels of C-reactive protein and IL-6.⁴⁶ Disrupted or diminished sleep may thus induce chronic systemic inflammation, which itself may contribute to cardiovascular disease and diabetes.

Oxidative Stress

Sleep deprivation is associated with increased total leukocyte counts⁴⁶ and increased neutrophil counts.^{47,48} Activated neutrophils are known to release potent oxidative enzymes from their azurophilic granules including *myeloperoxidase* (MPO), and epidemiologic studies have shown that increased leukocyte counts are associated with increased cardiovascular disease risk.^{49,50} MPO is an enzyme in the blood that catalyzes oxidation via the release of reactive halogenating and nitrating species. MPO is a marker of oxidative stress that has potent atherogenic properties via MPO-modified LDL, an oxidative species associated with increased cardiovascular risk.⁵¹ Thus it is interesting that both MPO and MPO-modified LDL levels are elevated in healthy young adults after a period of chronic sleep restriction and recovery. For example, after a period of five sleep-deprived nights in healthy young adults, MPO levels were elevated and MPO levels peaked on the first day of sleep recovery.⁵² These data suggest the notion that periods of chronic sleep deprivation and recovery may lead to cardiovascular disease via leukocyte-mediated elevations of pro-atherogenic oxidative biomarkers.

Dysautonomia

Disrupted sleep results in activation of the neuroendocrine stress response and an overall increase in sympathetic tone.⁵³ The two primary systems involved with the neuroendocrine stress response in humans and other organisms are the sympathoadrenal system and the hypothalamic-

pituitary-adrenal axis. Onset of sleep has been associated with a rapid decrease in plasma levels of epinephrine and norepinephrine as a result of decreased sympathetic output in humans and rodents.^{54,55} Both norepinephrine and epinephrine plasma levels have also been shown to be higher during wakefulness, considered a state of higher vigilance. Sleep disruption itself may be associated with the stress response, and additionally chronic sleep deprivation disrupts the circadian balance of autonomic tone via the sympathoadrenal system and the hypothalamic-pituitary-adrenal axis.^{56,57} Studies of heart rate variability, a useful tool for estimating autonomic tone, indicate a shift to a dominant state of parasympathetic tone compared with sympathetic tone in the heart during normal circadian sleep.⁵⁸ This notion is further supported by the observation that, during normal sleep compared with wakefulness, there is a decrease in systemic blood pressure. This phenomenon of “nocturnal dipping” is at least in part related to decreased sympathetic output during sleep.⁵⁹

During normal human sleep, glucocorticoid release follows a circadian pattern as directed by the suprachiasmatic nucleus of the hypothalamus. More particularly, glucocorticoid levels decrease after the onset of sleep and peak just before the end of sleep, helping to mobilize energy substrates. Disrupted sleep leads to altered glucocorticoid release secondary to stress activation of the hypothalamic-pituitary-adrenal axis. Studies have shown an overall modest increase in endogenous glucocorticoids in association with disrupted and restricted sleep in healthy volunteers.^{31,60} However, some studies have shown no association between the two and others have even shown a slight decrease in endogenous glucocorticoid release in relation to disrupted sleep.^{61,62} This paradoxical finding may be explained by overall global suppression of sympathetic activity in relation to fatigue and daytime sleepiness. The bulk of the literature indicates that disrupted or restricted sleep leads to dysautonomia with an overall shift to greater sympathetic tone.

Endothelial Dysfunction

Perhaps related to the oxidative stress and dysautonomia, sleep disturbance has been associated with endothelial dysfunction. The increase in reactive oxygen species leads

to increased expression of adhesion molecules that activate leukocytes. Studies in a rat model suggest that sleep deprivation can alter endothelial function and vasodilation via disruption in the pathways for nitric oxide synthase and cyclooxygenase.⁶³ Studies of sleep apnea patients have demonstrated a relationship with markers of endothelial dysfunction including circulating levels of the adhesion molecules intercellular adhesion molecule-1 and L-selectin.⁶⁴ There is also an association with increased vascular endothelial growth factor. These changes lead to abnormal vasodilatory responses, which can predispose to hypertension and cardiovascular disease.⁶⁵ In a recent systematic review, OSA was found to be an independent predictor of subclinical cardiovascular disease, as assessed by measures such as coronary artery calcification and brachial artery flow-mediated dilation.⁶⁶ The impact of sleep disturbance on endothelial dysfunction and cardiac events is undergoing investigation.

Key Points

- Sleep disruption is increasingly emerging as a major predictor of chronic disease and poor health.
- Poor sleep has been associated with short-term and long-term cognitive impairment.
- Poor sleep has been associated with immune dysfunction.

- Poor sleep has been associated with cardiometabolic implications such as increased risk for diabetes, hypertension, and coronary artery disease.
- Both inadequate sleep duration and excessive sleep duration have been associated with adverse health consequences.
- Sleep quality is poor in critically ill patients, and efforts to optimize ventilator synchrony and to decrease noise, disruptions, and air leaks may improve sleep and perhaps reduce delirium and improve immune function.

PERIOPERATIVE CONSIDERATIONS IN OSA**DISEASE MANAGEMENT STRATEGIES FOR OSA****INTRODUCTION AND DEFINITIONS**

Sleep-disordered breathing is a very common clinical problem. Pathologic changes in breathing during sleep may take the form of discrete episodes of absent (apnea) or reduced (hypopnea) breathing or of more sustained reductions in breathing during sleep compared with wakefulness (hypoventilation). The most common form of sleep-disordered breathing results from closure of the upper airway during sleep and is called *obstructive sleep apnea* (OSA). Apneas may also be due to transient loss of respiratory drive output from the central respiratory controller (central apnea). “Mixed apneas” are individual events that begin as central apneas but become obstructive. Mixed apnea should not be confused with the combination of pure obstructive and pure central events in the same patient during sleep. The latter situation is referred to as “complex sleep apnea.” Complex sleep apnea is used specifically when there is either a combination of obstructive and central events on the diagnostic sleep study or when central events emerge during titration of *continuous positive airway pressure* (CPAP) for obstructive sleep apnea. Sleep-associated hypoventilation is defined as a sustained reduction in breathing associated with an increase in PCO_2 or sustained decrease in arterial *oxygen saturation* (SO_2) of less than 90% during sleep without discrete apneas or hypopneas.

Fundamental to identifying sleep-disordered breathing is a description of breathing events that happen during sleep^{1,2} (Fig. 88-1). In adults an apnea is defined as a cessation of breathing that lasts longer than 10 seconds. *Apneas* are identified as being obstructive if there are sustained respiratory efforts during the event, usually identified by use of thoracic and abdominal respiratory inductance plethysmography bands, which demonstrate paradoxical thoracoabdominal motion. In contrast, during central apneas there is absence of respiratory effort during the event. *Hypopneas* are events associated with a reduction rather than complete cessation of airflow. These discrete reductions in ventilation may be associated with a fall in oxygen saturation or may terminate in association with a brief arousal from sleep (*microarousal*). Although the definition of apneas is well standardized, several different criteria have been used to identify hypopneas, based on the extent of flow reduction, degree of oxygen desaturation, and the presence of microarousal.¹⁻³ For example, the *American Academy of Sleep Medicine* (AASM) currently recognizes two alternate definitions of hypopnea² (Table 88-1). Another type of event is termed a *respiratory effort-related arousal* (RERA). These are episodes characterized by mild upper airway narrowing during sleep, with increased respiratory effort required to maintain a slightly reduced level of airflow not large enough to be scored as hypopnea.⁴ When the increased inspiratory effort required to maintain ventilation is associated with a microarousal, a RERA is scored (Fig. 88-2).

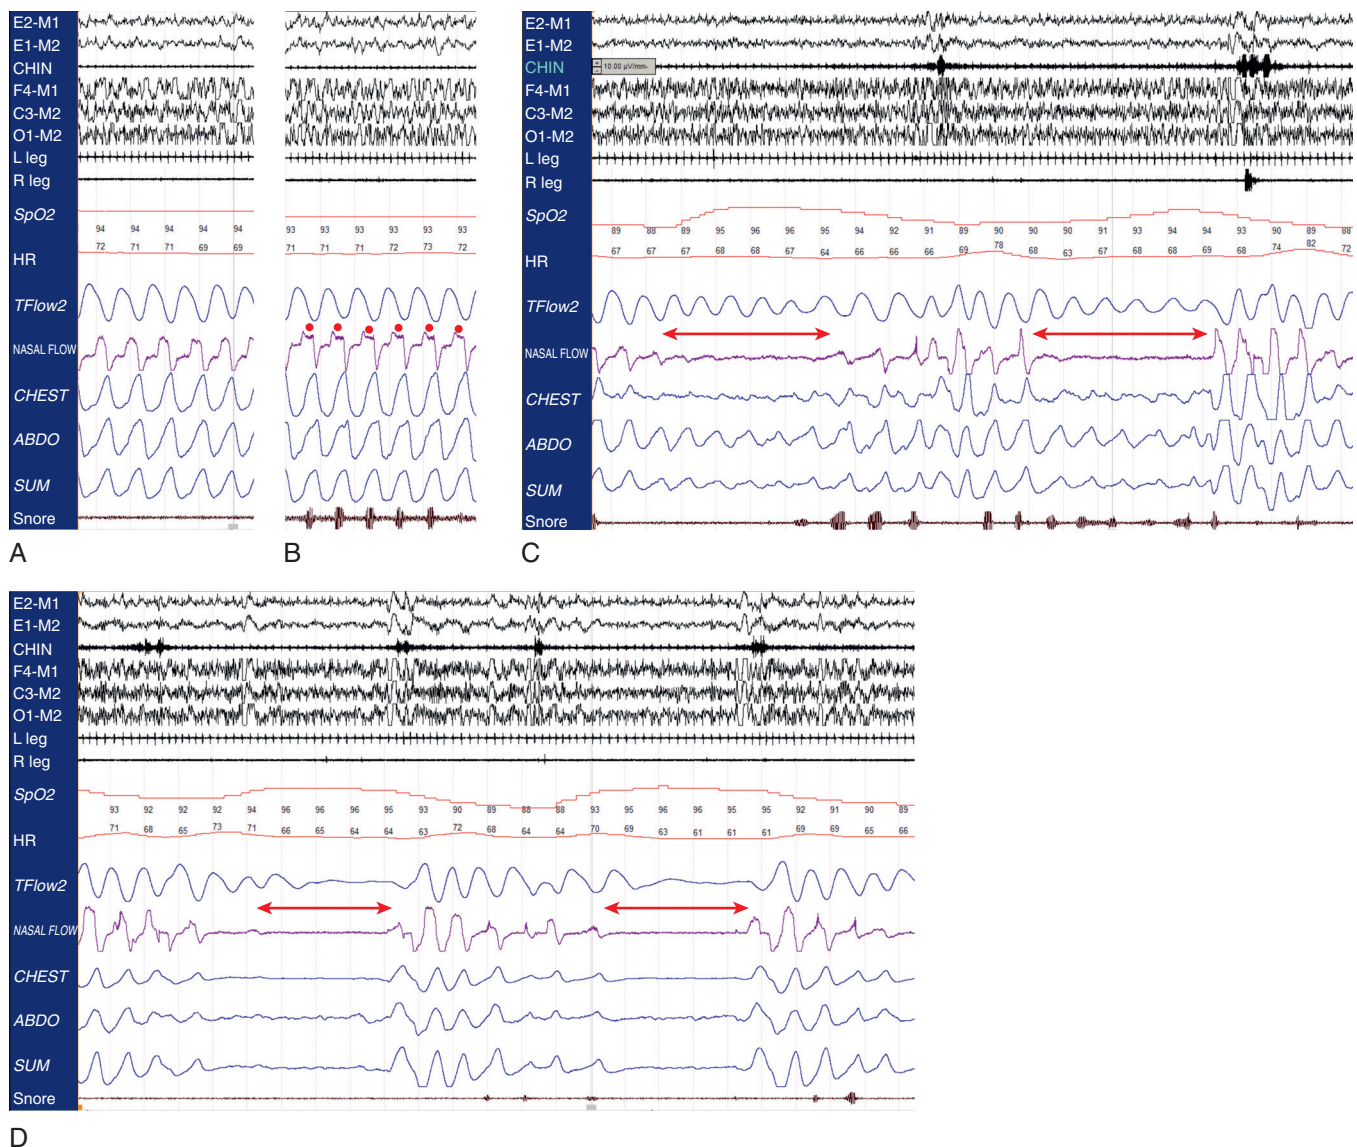

Figure 88-1 Polysomnographic tracings illustrating stable breathing (A), simple snoring (B), obstructive hypopneas (red arrows, C), and central apneas (red arrows, D). Note in **B** that the snores are shown as a microphone signal (Snore) along with an inspiratory flattening on the nasal pressure flow signal (red dots). Note in **C** that there is evidence of persistent airflow during events on the thermistor (TFlow2) signal while the nasal pressure signal shows no flow. The event is therefore scored as a hypopnea because flow must be absent on both signals to score an apnea (as in **D**). The events in **C** are considered obstructive because there is persistent effort during the event with paradoxical inward motion of the ribcage on the thoracic effort channel (CHEST). The events in **D** are considered central because the absence of airflow is accompanied by an absence of effort (CHEST, ABDO).

Traditionally detection of RERAs has required use of an esophageal pressure catheter to measure respiratory effort.⁵ However, with the advent of nasal pressure cannula for measurement of airflow, subtle reductions in flow, accompanied by airflow limitation identified as flattening of the inspiratory airflow signal, can now be used to score RERAs.² Changes in pulse transit time (the time from the onset of the electrocardiographic QRS complex to the pulse wave in the finger) also accurately reflect increasing effort and arousal.⁶ The scoring criteria for respiratory events recommended by the AASM are shown in Table 88-1.

The standard metric for assessment of OSA severity is the *apnea-hypopnea index* (AHI), which is calculated as the number of apneas and hypopneas during sleep divided by total sleep time. OSA severity is graded as follows: normal (no OSA; AHI < 5 episodes/hr), mild sleep apnea (AHI ≥ 5

and < 15 episodes per hour), moderate sleep apnea (AHI ≥ 15 and < 30 episodes per hour), and severe sleep apnea (AHI ≥ 30 episodes per hour). Current AASM criteria for *polysomnographic* (PSG) analysis also define the respiratory disturbance index as the number of apneas, hypopneas, and RERAs per hour of sleep.²

Several factors can influence the AHI value derived from PSG recordings.^{1,7-9} For example, the technology used to assess airflow has evolved from reliance on oronasal thermistor technology to addition of the nasal pressure signal, which is more sensitive for detection of mild reductions in airflow.⁷ The current prevalence estimates for OSA are derived from studies that used thermistor technology only.^{10,11} Addition of nasal pressure analysis would likely increase detection of respiratory events and thus OSA prevalence. Differences in hypopnea definitions can also lead to

Table 88-1 Definitions of Respiratory Events for Diagnostic Polysomnography

Apnea: An event lasting ≥ 10 sec characterized by $\geq 90\%$ reduction from pre-event baseline in oronasal thermistor airflow. An apnea is scored as:

- Obstructive, if there is continued or increasing respiratory effort throughout the event
- Central, if effort is absent throughout the entire event
- Mixed, if effort is initially absent, then resumes in the latter part of the event

There is no minimum desaturation or microarousal requirement for scoring of an apnea.

Hypopnea: An event lasting ≥ 10 sec characterized by a $\geq 30\%$ reduction from pre-event baseline in peak nasal pressure inspiratory airflow that is associated with:

- Definition 1A: Either a $\geq 3\%$ reduction in arterial oxygen saturation (SO_2) pre-event baseline or a microarousal
- Definition 1B: A $\geq 4\%$ reduction in arterial SO_2 from pre-event baseline value

The hypopnea is scored as *obstructive* if during the event there is any snoring, inspiratory airflow limitation, or paradoxical thoracoabdominal motion that was not present during pre-event breathing.

The hypopnea is scored as *central* if none of the events described above is present.

Respiratory effort-related arousal (RERA): A sequence of breaths lasting ≥ 10 sec that does not meet criteria for apnea or hypopnea, which is characterized by increasing respiratory effort or inspiratory flattening of the nasal pressure flow signal leading to arousal.

Hypoventilation: An increase in PCO_2 to > 55 mm Hg for ≥ 10 min or PCO_2 increase ≥ 10 mm Hg above awake supine values to > 50 mm Hg for ≥ 10 min.

Adapted from Berry RB, Brooks R, Garmaldo CE, et al: *The AASM manual for the scoring of sleep and associated events: rules, terminology and technical specifications, version 2.0*, Darien, IL, 2013, American Academy of Sleep Medicine.

Table 88-2 Epworth Sleepiness Scale

Situation	Chance of Dozing
Sitting and reading	
Watching TV	
Sitting inactive in a public place (such as a theater or meeting)	
Riding as a passenger in a car for an hour without a break	
Lying down in the afternoon when circumstances permit	
Sitting and talking to someone	
Sitting quietly after a lunch without alcohol	
In a car, while stopped for a few minutes in traffic	
Score = total (normal < 11)	

Instructions to patient:
“What is the chance that you would doze off or fall asleep (not just “feel tired”) in each of the following situations? Rate the chance for each situation. If you are never or rarely in the situation, please give your best guess for that situation.”
Chance of dozing: 0, never; 1, slight chance; 2, moderate chance; 3, high chance.

sizeable differences in measurement of OSA severity.^{8,9} In one analysis performed by the Sleep Heart Health Study investigators, varying the hypopnea scoring criteria (from no requirement for associated desaturation or arousal to a severe desaturation requirement) led to as much as a 10-fold difference in mean AHI value.⁸ This may therefore affect both the severity estimate and the presence versus absence of OSA based on AHI cutoff criteria. Thus it is essential in interpreting clinical reports of PSG studies or published research data that the criteria for respiratory event scoring be stated clearly and taken into account in interpreting the findings.

Not all patients with OSA will have symptoms related to the respiratory disturbance. The term *sleep apnea syndrome* is used to refer to the concurrence of OSA with symptoms referable to the respiratory disturbance, such as *excessive daytime sleepiness* (EDS).¹² The latter can be identified by subjective questionnaires. A commonly used questionnaire is the Epworth Sleepiness Scale,¹³ in which the respondent indicates the likelihood of dozing (scale from 0 to 3) in eight common circumstances associated with sleepiness (Table 88-2). A score of 11 or higher (out of 24) is commonly accepted as indicating excessive sleepiness.¹³ The *International Classification of Sleep Disorders*, third edition (ICSD-3) identifies a diagnosis of OSA in adults based on a AHI of 5 or higher with symptoms, or AHI of 15 or higher regardless of symptoms¹² (Table 88-3).

Another term used in the spectrum of obstructive sleep-disordered breathing is the *upper airway resistance syndrome*. Whereas this entity is now subsumed under “Obstructive Sleep Apnea” in ICSD-3, the term was originally used by Guilleminault and colleagues⁴ to describe patients with increased upper airway resistance during sleep, recurrent arousals, and daytime symptoms, but in whom conventional criteria for thermistor-based identification of hypopneas were not met (eFig. 88-1). The definition and identification of this syndrome has evolved in the ensuing years, and it is now commonly characterized as a

Figure 88-2 Sleep tracing illustrating respiratory effort-related arousals (RERAs). Note the flattening (flow limitation) on the nasal cannula pressure signal, with increasing inspiratory efforts reflected on the esophageal (pleural) pressure tracing. Electroencephalogram is not shown on this tracing but would demonstrate microarousal at the termination of the RERA events. Autonomic activation at the end of the events is evident from the pulse transit time and arterial blood pressure signals. (From Pepin JL, Guillot M, Tamisier R, Levy P. The upper airway resistance syndrome. *Respiration* 83[6]:559–566, 2012.)

Table 88-3 Definition of Adult Obstructive Sleep Apnea (OSA)

OSA is present when either A and B, or C are present:

A. At least one applies:

- The patient complains of daytime sleepiness, unrefreshing sleep, fatigue, or insomnia
- The patient awakens with breath-holding, gasping, or choking
- The bed partner reports loud snoring, breathing interruptions, or both during the patient's sleep
- The patient has been diagnosed with hypertension, mood disorder, cognitive dysfunction, coronary artery disease, congestive heart failure, stroke, atrial fibrillation or type 2 diabetes

AND**B. Sleep recording* shows the following:**

- Five or more predominantly obstructive respiratory events (obstructive or mixed apneas, hypopneas, or RERAs) per hour

OR**C. Sleep recording* shows the following:**

- Fifteen or more predominantly obstructive respiratory events (obstructive or mixed apneas, hypopneas, or RERAs) per hour

RERA, respiratory effort–related arousal.

*Sleep recording may be either laboratory polysomnography (PSG) or out of laboratory portable testing which usually does record signals to allow sleep staging. Respiratory event numbers are expressed per hour of sleep for PSG and per hour of recording for portable monitors. Portable monitors tend to underestimate event indices as compared with PSG as patients usually are not asleep for an entire recording period. Hypopneas associated with arousals and RERAs cannot be scored from portable monitors without sleep staging capability as arousals cannot be identified.

Adapted from *International classification of sleep disorders*, ed 3, Westchester, IL, 2014, American Academy of Sleep Medicine.

sleep-disordered breathing syndrome in which PSG shows more than 50% of events are RERAs. A recent review of the upper airway resistance syndrome is available.¹⁴

PATHOGENESIS OF OSA

The pathogenesis of OSA involves a complex interaction of factors, including altered upper airway anatomy tissue characteristics and neuromuscular function, sleep-related decrements in upper airway dilator muscle activity, attenuated protective dilator reflexes, and altered ventilatory and arousal responses to chemical and other respiratory stimuli (Fig. 88-3). Different factors may predominate in different individuals, yielding different OSA phenotypes. The upper airway in OSA closes only during sleep, indicating that sleep-dependent changes in output to the dilator muscles of the upper airway are clearly a fundamental mechanism. Airway collapse ensues when dilator muscle activity and compensatory reflexes are no longer sufficient to maintain patency of the compromised airway. The key elements of sleep-related influences on respiratory motor output are discussed in Chapter 85 and will not be covered here. Rather this section will focus on structural and functional changes in the upper airway that predispose to airway closure. Several comprehensive reviews of OSA pathogenesis are available.^{15,16}

UPPER AIRWAY SIZE

A variety of imaging methods have shown that upper airway dimensions are reduced in OSA.¹⁷ The reduction in airway caliber is predominantly in the lateral rather than anteroposterior dimension. Airway size may be compromised by alterations in bony structures such as a small

Factors affecting upper airway patency	Patency	Collapse
Anatomic configuration (bony structure, soft tissue, fat)	 Normal	 Reduced dimensions
Lung volume	Traction on upper airway	Lower lung volume; less traction
Lining fluid surface tension	Normal	Increased
Intraluminal pressure	Less negative	More negative
Extraluminal tissue pressure	Less positive	More positive
Airway collapsibility (P_{crit})	Lower	Higher
Sleep-related decrements in muscle activity	Normal, mild compared with wakefulness	Marked compared with heightened compensatory levels during wakefulness
Chemosensitivity	Normal	Blunted or heightened
Negative pressure reflexes	Mild sleep-related decrement	Blunted (latency, amplitude)
Dilator muscle activation	Adaptation	Injury, dysfunction
Denervation (sensory, motor)	Absent	Neural, muscular dysfunction
Edema: inflammation; nocturnal fluid shift	Absent	Altered airway caliber, tissue characteristics

Figure 88-3 Schema illustrating factors that favor upper airway collapse during sleep in obstructive sleep apnea (OSA). For explanation, see text and also Chapter 85. P_{crit} , critical closing pressure. (Adapted from Kimoff R: The upper airway. In Hamid Q, Shannon J, Martin JG, editors: *The physiologic basis of respiratory disease*, Hamilton, Canada, 2005, BC Dekker.)

retrognathic mandible¹⁸ or by increased volume of soft tissues (tongue, lateral walls).¹⁹ Although cross-sectional dimensions are reduced, airway length may be increased in OSA patients, with increased length predisposing to collapse.^{20,21} Upper airway caliber is also influenced by lung volume due to tracheal traction, so that in obese subjects, marked reductions in lung volume during recumbency can lead to reduced upper airway patency.^{22,23}

UPPER AIRWAY COLLAPSIBILITY

Due to a lack of rigid supporting structures, much of the human upper airway is a collapsible tube. Pressure-flow relationships in the airway have been modeled using the Starling resistor model, in which collapsibility is expressed as the *critical closing pressure* (P_{crit}). P_{crit} is measured during sleep by changing intraluminal pressure (e.g., lowering CPAP level in an OSA patient or applying negative pressure in a normal subject) and assessing flow reductions. A more negative P_{crit} denotes a less collapsible airway. Studies have shown a continuum of upper airway collapsibility in subjects with normal breathing ($P_{crit} < -10$ cm H₂O), nonapneic snoring (P_{crit} range, -10 to -5 cm H₂O), obstructive hypopnea (P_{crit} range, -5 to 0 cm H₂O), and obstructive apnea ($P_{crit} > 0$ cm H₂O).²⁴⁻²⁶ These values are for “passive” P_{crit} , which reflects the passive mechanical properties of the airway. Techniques are also available to measure “active” P_{crit} , which reflects active neuromuscular compensation for reduced intraluminal pressure. Active P_{crit} measurements demonstrate a significant impairment in neuromuscular compensation in OSA patients.^{26,27}

NEUROMUSCULAR FACTORS

Several factors may contribute to impaired neuromuscular upper airway function in OSA in addition to the attenuation of protective reflexes during sleep discussed in Chapter 85. Upper airway muscle function may be impaired in OSA, although this remains controversial.^{28,29} In response to the loading of the upper airway dilators, the muscles appear to adapt, and whereas contractility appears preserved in most patients, the muscles are more fatigable.³⁰ In some patients with severe OSA, muscles may be injured, leading to reduced contractility, as in the English bulldog model of OSA.³¹ There is also evidence for upper airway neuropathy in OSA, with evidence for sensory/afferent impairment^{32,33} and efferent neuropathy in the form of muscle denervation,^{34,35} both of which could impair neuromuscular compensatory responses.¹⁵

UPPER AIRWAY INFLAMMATION

There is increased inflammation in upper airway tissues in OSA, which may contribute to OSA pathogenesis.^{36,37} Tissue trauma from snoring, oxidative stress, acid-pepsin reflux, smoking, and alcohol could all lead to inflammation. Increased inflammation in turn may produce edema and airway narrowing, lead to changes in soft tissue composition (e.g., increased collagen deposition) and mechanics, adversely affect muscle contractility, and contribute to upper airway afferent and efferent neuropathy.^{15,37} Few studies to date have assessed the effects of anti-

inflammatory therapy on OSA, though inhaled nasal steroids have been shown to improve mild OSA.³⁸

FLUID SHIFT

Studies by Bradley and colleagues have provided evidence that spontaneous shifts in fluid volume from the legs to the neck during recumbency or sleep may play a role in the pathophysiology of OSA.³⁹ Cephalad displacement of fluid from the legs in normal subjects using shock pants increases neck circumference and pharyngeal resistance,⁴⁰ as well as upper airway collapsibility.⁴¹ The extent of spontaneous overnight fluid shift correlates with AHI in nonobese OSA subjects.⁴² In OSA patients with venous insufficiency, the use of compression stockings to prevent daytime fluid accumulation in the legs was associated with a significant reduction in nocturnal fluid shift and in AHI.⁴³ Consideration should therefore be given to this approach in managing OSA among older sedentary patients with venous insufficiency.

CLINICAL FACTORS PREDISPOSING TO OSA

OBESITY

There are strong links between obesity and OSA.^{44,45} Approximately 58% of patients with moderate to severe OSA are obese.⁴ Obesity may reduce upper airway caliber because of adipose tissue deposition as well as through a lung volume-dependent effect.²³ Obesity and OSA are both associated with oxidative stress and systemic inflammation, and the two conditions may interact to potentiate each other.⁴⁶ Weight change is associated with a change in AHI. In the Wisconsin cohort over 8 years' follow-up, a 10% increase in body weight was associated with a 32% increase in AHI and a sixfold increase in risk for developing an AHI of 15 or higher. A 10% weight loss was associated with a 26% reduction in AHI.⁴⁷ Weight-related changes in AHI are more marked in men than women.^{44,45} Despite the strong links between OSA and obesity, many obese individuals do not have OSA, and up to one third of OSA patients are not obese.

UPPER AIRWAY ANATOMIC ABNORMALITIES

Abnormalities that may predispose to OSA include marked craniofacial disproportion as is seen in Pierre Robin syndrome,⁴⁸ benign tonsillar hypertrophy, oropharyngeal malignancies,⁴⁹ macroglossia, and acromegaly.⁵⁰ Nasal obstruction may contribute to OSA⁵¹ by increasing negative inspiratory driving pressure to maintain airflow, which may contribute to dynamic oropharyngeal collapse. However, surgical correction of mechanical nasal obstruction alone typically has minimal effects on OSA severity.^{52,53}

GRAVITY/BODY POSITION

The frequency of OSA events may increase in the supine position compared with the lateral decubitus position because of the effects of gravity on upper airway size and shape. Positional OSA is commonly defined as a supine AHI

at least double that in the lateral position.⁵⁴ The duration of obstructive events and extent of associated oxygen desaturation may also worsen in the supine position.⁵⁵ Although prevalence estimates vary,⁵⁴ positional OSA has been identified in 49.5% of mild (AHI 5 to 15), 19.4% of moderate (AHI 15 to 30), and 6.5% of severe (AHI \geq 30) OSA patients.⁵⁶

GENETIC FACTORS

Studies in diverse populations have demonstrated familial propensity for OSA. The relative risk for OSA in a first-degree relative of an affected patient is approximately 2.0.⁵⁷⁻⁵⁹ Pedigree and twin studies indicate that the heritability of the AHI is approximately 35% to 40%.⁶⁰ Thus inquiring about a family history of snoring and other symptoms should be part of the routine evaluation of patients for OSA. Obesity, which is a major OSA risk factor, also has a genetic basis, and it is estimated that approximately 40% of the genetic variance in AHI is shared with pathways that mediate obesity.^{60,61} The remainder of heritability likely resides in genes controlling craniofacial structure, ventilatory control, sleep-wake patterns, and inflammation.^{58,59,62} Various techniques have been used to identify specific genetic pathways that mediate OSA and its complications. Although progress has been made, there are few findings with direct clinical impact. Several reviews of genetic studies in OSA are available.⁵⁷⁻⁵⁹

ENDOCRINE DISTURBANCES

OSA has been reported to be present in 25% to 35% of patients with untreated hypothyroidism.^{63,64} Predisposition to OSA may be due to increased mucopolysaccharide and protein deposition in upper airway tissues. Altered central respiratory control or neuropathic changes in upper airway muscles may also play a role. Thyroid replacement therapy improves OSA in many patients, though there may be residual sleep-disordered breathing that requires continued standard treatment.^{63,64} Although a clinical history suggesting hypothyroidism should be sought during evaluation of OSA patients, routine biochemical screening of all potential OSA patients is not warranted.⁶⁵

Sleep-disordered breathing is found in approximately 70% of patients with acromegaly.⁶⁶ Although OSA predominates, central sleep apnea may also be observed. Upper airway dimensions are reduced due to both soft tissue (glycosaminoglycan and collagen deposition, edema) and bony changes.⁵⁰ Upper airway myopathy may also play a role. Correction of the endocrine disturbances in acromegaly results in variable improvements in OSA; continued treatment with CPAP is often required.⁶⁴

OSA is found in up to 70% of women with polycystic ovary syndrome.⁶⁷ Potential mechanisms include hormonal changes (relative androgen excess) and increased central adiposity. Polycystic ovary syndrome is associated with a high rate of metabolic dysfunction. OSA may worsen metabolic function, and OSA treatment may improve metabolic parameters in these patients.⁶⁸ Clinicians managing patients with these endocrine disturbances should have a low threshold for requesting sleep studies if symptoms suggestive of OSA are present.

SMOKING

Cigarette smoking has been linked to snoring and OSA in cross-sectional epidemiologic studies.^{69,70} Although the Sleep Heart Health Study investigators found that smoking was less prevalent in OSA than non-OSA patients,⁷¹ analysis of a subset of the Wisconsin cohort study found a significant positive dose-response relationship between cigarette smoking and OSA severity.⁷² Possible mechanisms include worsening of upper airway inflammation and sleep-disruptive effects of nicotine producing respiratory instability.

ALCOHOL, DRUGS

Alcohol is known to worsen snoring and OSA. This may be due to direct effects on upper airway motor activity or to a deepening of sleep and impairment of arousal responses.⁷³ Other drugs with similar effects include muscle relaxants, sedative-hypnotics, and opioids, although the latter may also produce central and/or complex sleep apnea. Pharmacologic effects on upper airway motor control have been reviewed.⁷⁴

EPIDEMIOLOGY OF OSA

PREVALENCE

The first major community-based assessment of OSA prevalence was the Wisconsin Sleep Cohort Study, which reported the prevalence of OSA syndrome (AHI \geq 5 events per hour with daytime sleepiness) as 4% in men and 2% in women.⁷⁵ The prevalence of AHI of 15 or higher regardless of symptoms was 9% in men and 4% in women. Although other prevalence estimates have varied somewhat based on ethnicity, recruitment methods, technology used to record airflow, and definitions of hypopnea, other studies performed in the United States, Australia, Asia, and Spain have yielded similar values. However, it is important to note that, since the original estimates published in the early to mid-1990s, obesity has increased markedly in the United States and other Western countries.⁷⁶ Given the links between OSA and obesity, the earlier figures likely now underestimate the true prevalence. The Wisconsin Cohort investigators published updated estimates of OSA prevalence⁷⁷ with OSA syndrome (AHI \geq 5 events per hour with Epworth sleepiness score \geq 11) estimated at 14% in men and 5% in women 30 to 70 years of age. OSA is therefore highly prevalent in the general population.

GENDER DIFFERENCES

Epidemiologic studies have consistently demonstrated that OSA is two to three times more prevalent among men than women. Several factors may account for this male predominance, including differences in body fat distribution, upper airway anatomy (length, cross-sectional area) and collapsibility, and a protective effect of female sex hormones. The latter is supported by the observation that OSA is approximately three times more prevalent among postmenopausal than premenopausal women.^{78,79} However, the

mechanisms by which sex hormones affect OSA remain unclear. Epidemiologic studies suggest that hormone replacement therapy may have a protective effect,^{78,80} but hormone replacement appears to have little impact on OSA once present.⁸¹

ETHNICITY

Most of the data on OSA prevalence are derived from predominantly white populations, though several studies have addressed OSA prevalence in African American, Hispanic, and Asian populations. In African Americans, overall OSA prevalence is similar to that in whites,⁸² although prevalence is comparatively higher among African Americans younger than 25⁸³ or older than 65 years of age.⁸⁴ Initial reports suggested that symptoms of OSA were more prevalent among Hispanics than whites,^{85,86} but a more recent study found similar rates of OSA.⁸⁷ Several studies^{88,89} have shown that OSA prevalence in Asians is comparable to whites, despite a lower prevalence of obesity among Asians. Although obesity remains an important risk factor for OSA among Asians, craniofacial structure may play a more prominent role in OSA pathogenesis.^{88,89} Studies on ethnicity and OSA may be confounded by socioeconomic and residential factors. Poor socioeconomic status has been linked to OSA risk among children.^{90,91} Living in poor neighborhoods is associated with shorter sleep time and increased sleep disruption; air quality may also be worse, which could contribute to worsening of OSA through increased airway inflammation.⁹² CPAP compliance appears to be lower in African American patients, which may be related to socioeconomic status⁹³ and shorter sleep duration.⁹⁴

AGING

The prevalence of OSA increases with age through midlife. In the update from the Wisconsin Sleep Cohort, the estimated prevalence of OSA (AHI ≥ 5 with Epworth sleepiness score ≥ 11) among men was 12% for age 30 to 49 and 18% for age 50 to 70 and among women 3% for age 30 to 49 and 8% for age 50 to 70.⁷⁷ Studies evaluating OSA prevalence in individuals older than 65 years have reported a high incidence of OSA ($>50\%$). In one sample of community-dwelling men and women 65 years or older, 81% had an AHI of 5 or higher, and 62% had an AHI of 10 or higher.⁹⁵ In another study the *odds ratio* (OR) for having an AHI of 10 or higher was 6.6 (95% *confidence interval* [CI], 2.6 to 16.7) for men 65 to 100 years, compared with 20 to 44 years.⁹⁶ The comparable OR for women for an AHI of 15 or higher was 6.8 (95% CI, 0.8 to 25.9). Although it is clear that elderly patients with symptomatic OSA benefit from treatment, controversy exists with respect to the adverse health consequences of OSA in older adults.^{97,98} Randomized controlled trials evaluating effects of OSA treatment in older adults are required to advance knowledge in this area.

PREGNANCY

A growing body of data indicates that OSA may develop or worsen over the course of pregnancy.⁹⁹ Although there are no large-scale prospective epidemiologic PSG studies in pregnant women, based on symptoms of OSA (e.g., snoring)

and witnessed apneas, together with limited PSG studies, OSA may be present in up to 20% of pregnant women by the third trimester.⁹⁹ This is clinically relevant in that maternal OSA appears to contribute to gestational hypertension and preeclampsia, gestational diabetes, and possibly low infant birth weight.¹⁰⁰

DIAGNOSIS OF OSA

QUESTIONNAIRES/PREDICTION EQUATIONS

Several questionnaires such as the Berlin¹⁰¹ and Stop-BANG¹⁰² questionnaires have been developed to grade OSA risk. Clinical prediction models that incorporate symptoms and anthropometric measurements (e.g., body mass index, neck circumference) have been developed.¹⁰³⁻¹⁰⁷ These models tend to be relatively sensitive (76% to 96%) but not very specific (13% to 54%) when compared with PSG.¹⁰⁸ Thus, although questionnaires or prediction models are useful for screening or estimating pretest probability, objective sleep recording is required to establish a diagnosis of OSA (Fig. 88-4A).

LABORATORY POLYSOMNOGRAPHY

The gold standard test for OSA has long been considered to be in-laboratory, technologist-attended complete overnight PSG, referred to as “type 1 sleep testing.” Standards for the performance and analysis of full PSG have been established by the AASM.² Type 1 recordings include monitoring of electroencephalography, electro-oculography, chin electromyography, electrocardiography, oronasal airflow and snoring, pulse oximetry, thoracic and abdominal movement, body position, and tibialis anterior electromyography for scoring periodic leg movements (see Fig. 88-1). Infrared video monitoring is also used to record complex behaviors and movements to diagnose parasomnias. Sleep-wake state is scored using electroencephalography, electrooculography, and electromyography signals. Respiratory events are scored based on airflow, thoracoabdominal motion, and oximetry signals using the criteria described in Table 88-1. PSG records should be scored manually by trained technologists according to standard criteria² and summary data on sleep, respiratory, and other associated events generated in tabular and graphic summary format.

UNATTENDED SLEEP STUDIES

Although complete in-laboratory PSG is the gold standard for OSA diagnosis, there is limited access to this resource in many locations.¹⁰⁹ There are now “out-of-center” or portable sleep testing options available that are adequate for diagnosis of OSA in many instances. In addition to type 1 sleep testing (in-laboratory PSG) there are three other types of sleep testing defined by the AASM based on number of channels recorded. Type 2 PSG testing, which involves complete PSG performed in an unattended, nonlaboratory setting, has been used in population-based studies¹¹ and has clinical utility when complete PSG recording is desirable but the patient cannot come to the sleep laboratory (e.g., intensive care unit or disabled patients). Type 3 monitors acquire

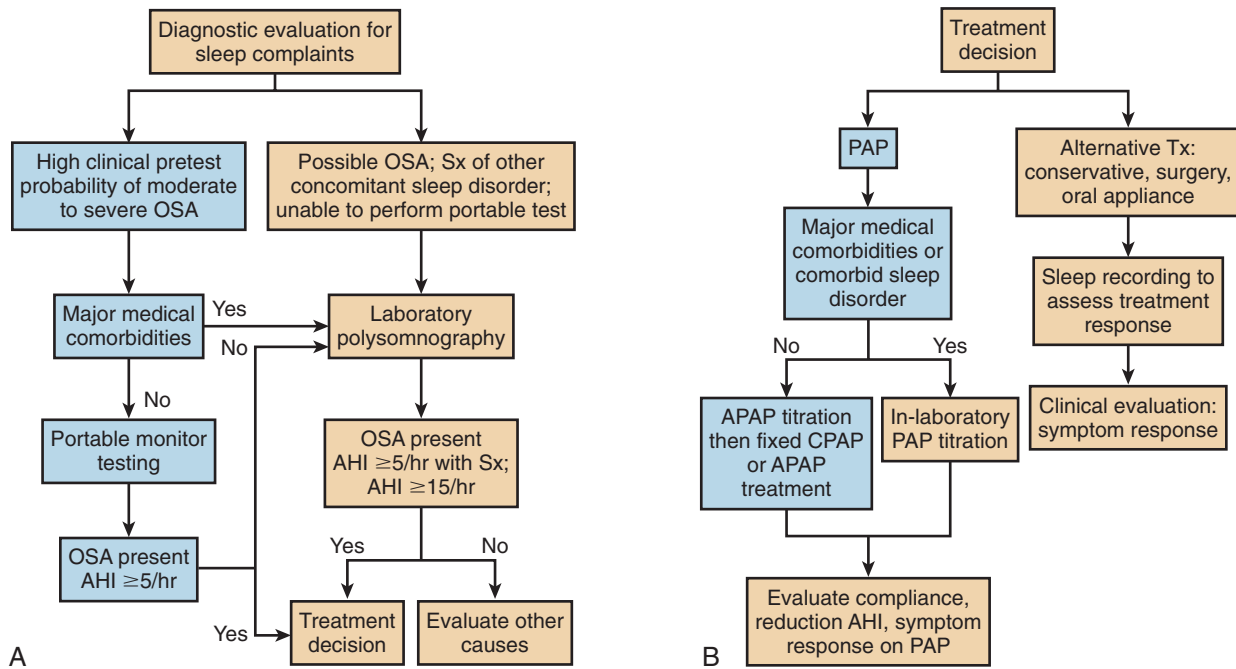

Figure 88-4 Schema illustrating an approach to diagnosis (A) and treatment (B) of OSA. An ambulatory pathway for patients with symptomatic moderate to severe OSA without other major comorbidities is shown in blue. AHI, apnea-hypopnea index; APAP, auto-PAP; CPAP, continuous positive airway pressure; PAP, positive airway pressure; Sx, symptoms; Tx, treatment.

respiratory airflow (nasal pressure and/or oronasal thermistor), respiratory effort, oximetry, and often snoring and body position (eFig. 88-2). Type 4 monitors record oximetry and sometimes one other signal such as airflow, thus yielding less information than type 3 monitors. Type 3 devices in particular are being increasingly used for the diagnosis and management of OSA. Recent guidelines recommend use of portable monitoring for evaluation of moderate- to high-pretest probability patients.¹¹⁰ Positive test results in such patients will rule in a diagnosis of OSA, whereas negative test results do not exclude more subtle forms of disease, and complete PSG should then be performed. Current guidelines do not recommend the use of portable monitoring for OSA diagnosis in the presence of major medical comorbidities or for diagnosis of sleep hypoventilation or central sleep apnea. However, for patients with moderate to severe OSA, data show that the use of portable monitors in ambulatory-based clinical management algorithms results in treatment adherence and clinical outcomes similar to conventional type 1-based approaches¹¹¹ (see “Disease Management Strategies for OSA” section later).

CLINICAL PRESENTATION OF OSA

SYMPTOMS, SIGNS

The classic clinical presentation of OSA is a history of heavy habitual snoring and EDS. However, OSA is a heterogeneous condition and may present with a variety of manifestations, and some patients with even moderate to severe OSA have few if any symptoms. OSA symptoms typically develop over many years in association with aging, weight gain, or onset of menopause and may be underappreciated by the patient.

Table 88-4 Symptoms of Obstructive Sleep Apnea

NOCTURNAL

Heavy, habitual snoring
Apneas witnessed by bed partner
Nocturnal choking
Nocturia
Restless sleep
Sweating
Erectile dysfunction
Gastroesophageal reflux
Unrefreshing sleep
Headache upon awakening

DAYTIME

Excessive daytime sleepiness
Difficulty concentrating
Memory loss
Irritability, personality change
Depressive symptoms
Fatigue

A comprehensive sleep history should be obtained in evaluating patients to assess not only features of OSA but the impact of sleep habits and other potential sleep disorders on clinical symptoms.

Patients with OSA should be questioned about having symptoms at night or during the day (Table 88-4). When possible, the spouse or partner should be questioned as well. During sleep most OSA patients manifest loud, disruptive snoring, which may lead the spouse to sleep in a separate room. Snoring is not a specific symptom for OSA and has a high prevalence in the general population. An important finding is a report by the bed partner of witnessed apneas. Although the frequency or duration of events reported may

not be accurate, a description of episodes during which breathing stops, followed by loud gasping or snoring is highly suggestive of OSA. Patients themselves are often unaware of apneic episodes, and it is surprisingly uncommon for patients to report nocturnal choking or shortness of breath upon awakening. The differential diagnosis for nocturnal choking includes paroxysmal nocturnal dyspnea related to heart failure and Cheyne-Stokes respiration, nocturnal asthma, laryngospasm (idiopathic or due to acid-pepsin reflux), orthopnea due to diaphragm dysfunction, or insular cortical seizures.¹¹² Most patients with OSA do not complain of insomnia, which when present often appears to be a separate process because OSA treatment does not generally reduce complaints of insomnia. However, OSA may rarely present with prominent insomnia symptoms that respond to OSA treatment. Other nocturnal symptoms of OSA include restless sleep, nocturia, enuresis (in severe cases), diaphoresis, and reduced libido and impotence. These symptoms also respond to OSA treatment, suggesting a causal link. Patients may complain of dry mouth upon awakening and a feeling of awakening unrefreshed. Morning headache may be present, which may be associated with nocturnal hypercapnia due to concomitant obesity hypoventilation.

The cardinal daytime symptom of OSA is EDS,¹¹³ defined as a propensity to fall asleep in unwanted situations during normal waking hours. EDS may develop insidiously and be underrecognized by the patient, with many patients describing symptoms of fatigue or lack of energy rather than sleepiness per se.¹¹⁴ Patients undergoing evaluation for OSA should be asked whether they have experienced drowsiness while driving or have fallen asleep at the wheel, because OSA increases the risk for crashes or near misses.^{115,116} Other symptoms of OSA include cognitive impairment such as difficulty with concentration or memory loss, mood disturbances such as irritability or depression, and impaired quality of life (discussed in “[Neurocognitive Complications of OSA](#)” section later).

MEASUREMENT OF SLEEPINESS

Questionnaires

The most commonly used questionnaire to quantify daytime sleepiness is the Epworth sleep questionnaire described earlier (see [Table 88-2](#)).¹³ Values of 11 or higher indicate excessive sleepiness. The Stanford Sleepiness Scale¹¹⁷ asks subjects to rate their degree of sleepiness at a single moment in time, such as just prior to a multiple sleep latency test. Choices range from “feeling active and vital, alert wide awake” to “almost in reverie, sleep onset soon.” This scale has been used more commonly in research, and normative clinical values have not been established, limiting its applicability.

Objective Sleepiness Measurements

Objective measurements can be made in the sleep laboratory during a series of scheduled daytime nap sessions to measure either physiologic sleepiness (multiple sleep latency test) or the ability to remain awake (maintenance of wakefulness test).^{118,119} A more accessible behavioral test that does not require PSG recording (Osler Test) has been found

Table 88-5 Differential Diagnosis of Excessive Daytime Sleepiness

Insufficient sleep (behaviorally induced)
Hypersomnia of central origin
Narcolepsy

REM, rapid eye movement.

to approximate findings on the maintenance of wakefulness test.^{120,121}

DIFFERENTIAL DIAGNOSIS OF EXCESSIVE SLEEPINESS

Although EDS is a common symptom of OSA, it is important to consider other potential causes of sleepiness ([Table 88-5](#)). The commonest cause of EDS is insufficient sleep duration. This may be due to poor sleep or social habits, the demands of work and family life, unfavorable sleeping environment, or other factors. It is therefore essential to obtain details of usual bedtime, time to fall asleep, number and duration of nocturnal awakenings, usual waking time, and whether wakening is spontaneous or requires one or more alarms. The regularity and timing of work and sleep schedules should also be ascertained. Short sleep duration during the week, with recovery sleep time on weekends is often a sign of insufficient sleep. When habitually present for 3 months or longer, this is termed “insufficient sleep syndrome.”¹² Management involves altering the sleep schedule on a consistent basis to provide adequate nocturnal sleep.

Central Disorders of Hypersomnolence

Other medical sleep disorders may also produce EDS.¹² These include *central disorders of hypersomnolence*, the most common of which is narcolepsy. Narcolepsy typically presents in the second or third decade of life and is characterized by a tetrad of symptoms, including daytime sleepiness, cataplexy, hypnagogic or hypnopompic hallucinations (hallucinations that take place in the transition between wakefulness and sleep), and sleep paralysis.^{122,123} Narcolepsy is a disorder of *rapid eye movement* (REM or stage R) with an “unpackaging” of REM phenomena so that aspects of REM sleep become apparent during wakefulness. Cataplexy is the sudden loss of muscle tone, as takes place in REM sleep, which is precipitated by emotion (laughter, anger, surprise) during wakefulness. Cataplexy is highly specific to narcolepsy and is a virtually pathognomonic symptom, although narcolepsy can be seen without

cataplexy. The atonia of cataplexy can be intense, leading to collapse, and can mimic syncope, though there is no true loss of consciousness. Cataplexy is associated with objective transient areflexia. Hypnagogic or hypnopompic hallucinations are vivid dreams typically with a strong visual component that are experienced either at sleep onset or when awakening from sleep. Individuals with sleep paralysis wake up from sleep unable to move, because they are emerging from REM sleep and the REM-associated atonia has not been switched off.^{122,123} Although particularly common in narcolepsy, sleep paralysis may also be experienced by otherwise healthy individuals.

Excessive sleepiness in narcolepsy is commonly treated with stimulant medication.^{124,125} Modafinil (Provigil) is the drug of choice. When ineffective, alternate stimulants are methylphenidate (Ritalin) or amphetamine preparations.¹²⁴ Improvements in EDS can be associated with improvement in other symptoms such as cataplexy and sleep paralysis, though specific medication may be required. Cataplexy is treated with antidepressants (tricyclic, selective serotonin-noradrenalin reuptake and monoamine oxidase inhibitor classes).^{124,125} Sodium oxybate (Xyrem) is approved for treatment of cataplexy and may also improve nocturnal sleep quality and EDS, although its use is limited by cost and potential side effects.¹²⁶

Periodic Hypersomnia

Klein-Levin syndrome is a rare cause of EDS that usually presents in adolescence and is characterized by intermittent episodes of intense hypersomnia with normal intervening sleep and alertness.^{12,125} The episodes may last for days, and patients may sleep for up to 20 hr/day. Episodes are associated with behavioral abnormalities, including binge eating and hypersexuality. Treatment is usually supportive during the episodes, with a limited role for stimulants; lithium may be effective in some cases.¹²⁵

Idiopathic Hypersomnia

This disorder is a diagnosis of exclusion and is characterized by persistent marked excessive sleepiness despite documented adequate sleep duration and hygiene, frequent daytime napping, subjectively uninterrupted nocturnal sleep, and normal nocturnal PSG recording, without symptoms of another sleep disorder or medical cause for hypersomnolence.¹² Although most patients have prolonged nocturnal sleep, some may not. The ICSD-3 does not distinguish between these two variants.¹² Management is with stimulant medication similar to narcolepsy, although symptoms may be more difficult to control.^{124,125}

Sleep-Related Movement Disorders

Movement disorders during sleep may cause sleep disruption and EDS. The most common is the *restless legs syndrome* (RLS), which is characterized by an urge to move the legs usually accompanied by uncomfortable or unpleasant sensations in the legs that (1) gets worse with periods of physical inactivity or rest, (2) is partially or totally relieved by movement such as walking or stretching, and (3) is worse or is felt only in the evening or night. The timing of symptom onset is such that the patient has difficulty falling asleep until the uncomfortable sensations and urge to move subside, which may be only after 2 to 3 hours after bedtime.

There are several factors that can precipitate or exacerbate RLS, the most common of which is iron deficiency. Serum iron and ferritin levels should be checked in all RLS patients. Caffeine, stimulants, and other medications may exacerbate RLS. RLS is common in renal dialysis and congestive heart failure patients and in patients with neuropathic disorders and may emerge or worsen during pregnancy.¹²⁷ Familial RLS has been described. Genetic studies have identified several loci linked to RLS, though to date these have not led to major insights into etiology, prevention, or treatment.¹²⁸

Treatment of RLS^{129,130} first involves correction of potential precipitating factors, in particular iron replacement if stores are low. A variety of medications may be used to treat RLS, including dopamine agonists such as pramipexole (Mirapex) and ropinirole (Requip),¹³¹ as well as anticonvulsants such as gabapentin and pregabalin.¹³⁰⁻¹³²

Circadian Rhythm Sleep-Wake Disorders

This set of clinical disorders is characterized by disturbances of the internal “biologic clock”¹³³ so that sleep is usually normal, but takes place at abnormal times.¹³⁴ The most common disturbance is delayed sleep-wake phase disorder.^{12,134} Affected individuals are unable to fall asleep until the early morning hours (e.g., 3 AM or later), sleep normally once asleep, and awaken late in the morning (e.g., 11 AM). If able to follow their “natural” sleep schedule, there are few daytime symptoms. However, when work or school imposes a different schedule, sleep time is restricted and daytime sleepiness ensues. Management of delayed sleep-wake phase disorder includes interventions to shift the biologic clock, such as administration of melatonin in the evening and exposure to bright light in the morning.^{134,135} Although changes in sleep schedule can be achieved, the effects may not be dramatic, and patients tend to revert easily to a delayed schedule if circadian measures are not rigorously maintained. Some patients choose occupations or work schedules that are compatible with their delayed phase.

Other circadian disorders include advanced sleep-wake phase disorder, in which sleep begins in the early evening, with early morning awakening. Treatment includes sleep schedule modifications and bright light exposure in the evening.¹³⁵ Jet lag disorder results from circadian misalignment because of travel across time zones with subsequent sleep disruption and daytime symptoms.¹³⁶ Management includes sleep scheduling, appropriately timed light therapy, and possible use of melatonin.^{134,135} Shift work disorder is characterized by more than 1 month of excessive sleepiness during scheduled work time, and insomnia during scheduled sleep times in the context of nonconventional and/or rotating work schedules.¹² Management includes optimizing the sleep environment and sleep schedule, preshift napping, bright light exposure during night shifts, and avoidance of bright light during the return trip home in the morning. Evidence supports the use of melatonin and judicious use of hypnotics to promote sleep, and modafinil and caffeine to promote wakefulness during work.¹³⁵

Other Conditions and Medications

Many medical conditions may be associated with sleep disruption and/or result in excessive sleepiness. These include

nocturnal respiratory disease with nocturnal cough or dyspnea, gastroesophageal reflux, nocturnal urinary frequency, chronic renal failure, various infectious diseases, and chronic pain syndromes.¹³⁷ Psychiatric disorders such as depression may present with excessive sleepiness. Numerous medications can affect nocturnal sleep quality and/or contribute to excessive sleepiness. Thus medication history and potential side effects should be carefully assessed.

NEUROCOGNITIVE COMPLICATIONS OF OSA

PATHOPHYSIOLOGY

A majority of apnea and hypopnea events terminate in association with arousal (see Fig. 88-1). Thus recurrent respiratory events over the course of the night lead to marked disruption of sleep continuity or sleep fragmentation. OSA is also typically associated with a reduction in the duration of deeper, more “restorative” sleep, including stage N3 (slow-wave) and stage R (rapid eye movement) sleep. These characteristic changes in sleep architecture are one factor leading to EDS and other neurocognitive sequelae of OSA. Application of nasal CPAP to treat OSA restores sleep continuity and may be associated acutely with a rebound increase in N3 and stage R sleep, which patients perceive as improved sleep quality.¹³⁸

Although respiratory-related sleep fragmentation alone (i.e., obstructive events without associated oxygen desaturation) can produce EDS, in studies of moderate to severe OSA, sleepiness and other neurocognitive sequelae correlate more closely with OSA-associated hypoxemia than with measures of sleep disruption.^{16,113,139} Studies in mice of cycling intermittent hypoxia mimicking OSA showed that severe hypoxia can produce excessive sleepiness, which persists up to 6 months following return to normoxia.¹⁴⁰ Veasey and colleagues identified neuronal injury in specific wake-promoting areas (monoaminergic neurons in locus coeruleus, periaqueductal gray) in these mice and have shown that injury is mediated by *nicotinamide adenine dinucleotide phosphate*, reduced form (NADPH) oxidase-dependent oxidative injury.^{140,141} Nair and colleagues¹⁴² demonstrated that intermittent hypoxia in mice also induces deficits in learning and memory, with the hippocampus being a particular site of neuronal injury. Neuroimaging studies in OSA patients have demonstrated changes in the hippocampal region and in other areas that subserve cognitive functions known to be impaired in OSA.^{143,144} It is therefore likely the hypoxia-reoxygenation associated with human OSA may produce sleepiness and other neurocognitive changes through similar pathways to those identified in experimental animals. However, debate continues concerning the relative roles of sleep fragmentation and hypoxic-mediated injury in producing OSA-related neurocognitive deficits.^{145,146}

Excessive sleepiness in OSA patients may also be influenced by factors other than those directly related to OSA itself. In addition, several studies have demonstrated that sleep schedule, obesity per se, and depression may all contribute to symptoms of sleepiness in OSA patients.^{147,148}

EXCESSIVE SLEEPINESS, REDUCED PERFORMANCE, AND TRAFFIC /WORKPLACE COMPLICATIONS

EDS is the most common symptom of OSA and can have profound adverse effects on quality of life, social relationships, and professional safety and performance. Patients with untreated OSA and daytime sleepiness are at significantly increased risk for motor vehicle crashes. Two meta-analyses^{115,149} have identified a twofold to threefold increase in risk for vehicular crashes among patients with untreated OSA (e.g., OR, 2.4; 95% CI, 1.2 to 4.9¹¹⁵). A recent meta-analysis found that treatment with positive airway pressure for severe OSA decreased the risk ratio for motor vehicle crashes to 0.28 (95% CI, 0.22 to 0.35),¹⁵⁰ translating into a reduction of between 65% and 78% in crash rate with OSA treatment.

There are important public safety and medicolegal implications of OSA for the practicing physician. The American Thoracic Society has recently published an updated practice guideline on OSA, sleepiness, and crash risk.¹¹⁶ Although the prediction of crash risk in individual OSA patients is imprecise, it is important to identify high-risk patients with symptoms of excessive sleepiness and a previous crash or near miss due to sleepiness. Such individuals should be warned of the dangers of driving before treatment, undergo diagnostic sleep testing within 1 month, and start CPAP treatment following a positive diagnostic test.¹¹⁶ Clinicians should also familiarize themselves thoroughly with legal requirements in their jurisdiction for reporting of OSA and driving restrictions.

One area of particular concern is the increased rate of motor vehicle crashes among commercial drivers.^{151,152} Several studies have shown a high prevalence of OSA among commercial drivers.¹⁵³⁻¹⁵⁵ Although no study to date has demonstrated that OSA leads to increased accident rates specifically among commercial drivers, extension from the general OSA driving literature, combined with the long distances driven commercially raises substantial concern. Screening for OSA is recommended as part of the general medical evaluation for commercial drivers.¹⁵¹ However, such screening relies heavily on self-reporting of sleepiness and OSA symptoms by drivers, who are known to under-report due to concerns about work restrictions.¹⁵⁵ One study suggests that drivers may be more likely to report symptoms if they can do so anonymously online.¹⁵⁶ A multisociety statement includes recommendations concerning OSA screening of commercial drivers and assessment of fitness for duty and return to work following OSA treatment.¹⁵¹

COGNITIVE IMPAIRMENT

OSA is associated with cognitive impairment.¹⁴⁴ OSA produces impairments in attention and vigilance, visuospatial construction abilities, verbal episodic and visuospatial memory, and subdomains of executive function.¹⁵⁷⁻¹⁵⁹ Treatment of OSA can improve global cognitive function, attention/vigilance, verbal and visual memory, and executive function.^{157,159} Most studies have evaluated treatment effects after only a few months, however, so that long-term effects are unknown. The *Apnea Positive Pressure Long-term*

Efficacy Study (APPLES) assessed domains of cognitive function in OSA at 2 and 6 months of effective versus sham CPAP treatment.¹⁶⁰ Improvement was observed in a measure of executive and frontal lobe function at 2 months but was not sustained at 6 months. However, baseline function was high in study participants; further studies on long-term treatment in OSA patients with more marked baseline cognitive impairment are required.

DEPRESSION

Depressive symptoms are common in OSA patients and are more prevalent in women.¹⁶¹ Although epidemiologic studies indicate that the presence of untreated OSA is a risk factor for developing depression,¹⁶² the interaction between depression and OSA remains poorly understood.^{161,163} Depression may worsen symptoms of sleepiness and fatigue in OSA.¹⁴⁸ Although responses are not uniform, some studies report improvement in depression scores with OSA treatment.¹⁶³ The prevalence of OSA among patients with clinical depression is not known,¹⁶¹ but symptoms of OSA should be sought in patients with depression, given the potential beneficial effects of OSA treatment.

OTHER COMPLICATIONS

OSA can lead to erectile dysfunction,^{164,165} which has been linked to nitric oxide and NADPH-related pathways in animal models.^{166,167} Treatment of OSA may improve erectile function.¹⁶⁸

The effects of OSA can have a substantial negative impact on patients' overall quality of life. Disease-specific indices have been developed to assess the impact of OSA on quality of life, including the Functional Outcomes of Sleep Questionnaire,¹⁶⁹ Calgary Sleep Apnea Quality of Life Index,¹⁷⁰ and the Quebec Sleep Questionnaire.¹⁷¹ Studies using these measures indicate that OSA-related impairment can be substantial, and that OSA treatment can significantly improve quality of life.^{172,173}

CARDIOMETABOLIC COMPLICATIONS OF OSA

PATHOPHYSIOLOGY

Obstructive apneas and hypopneas trigger a cascade of acute hemodynamic, autonomic, biochemical, inflammatory, and metabolic effects that can produce both acute and long-term changes in cardiovascular function^{174,175} (Fig. 88-5). Autonomic tone is altered during apneas, with acute sympathetic-mediated increases in blood pressure and heart rate observed at airway reopening¹⁷⁶ (Fig. 88-6). Blood vessel shear stress is also increased due to hypertension and hemodynamic surges. The negative intrathoracic pressures generated during obstructed inspiratory efforts increase left ventricular transmural pressure and therefore afterload, a stimulus for ventricular hypertrophy and an excessive load for a compromised ventricle.¹⁷⁵ The increased sympathetic neural activity during apneas may persist into

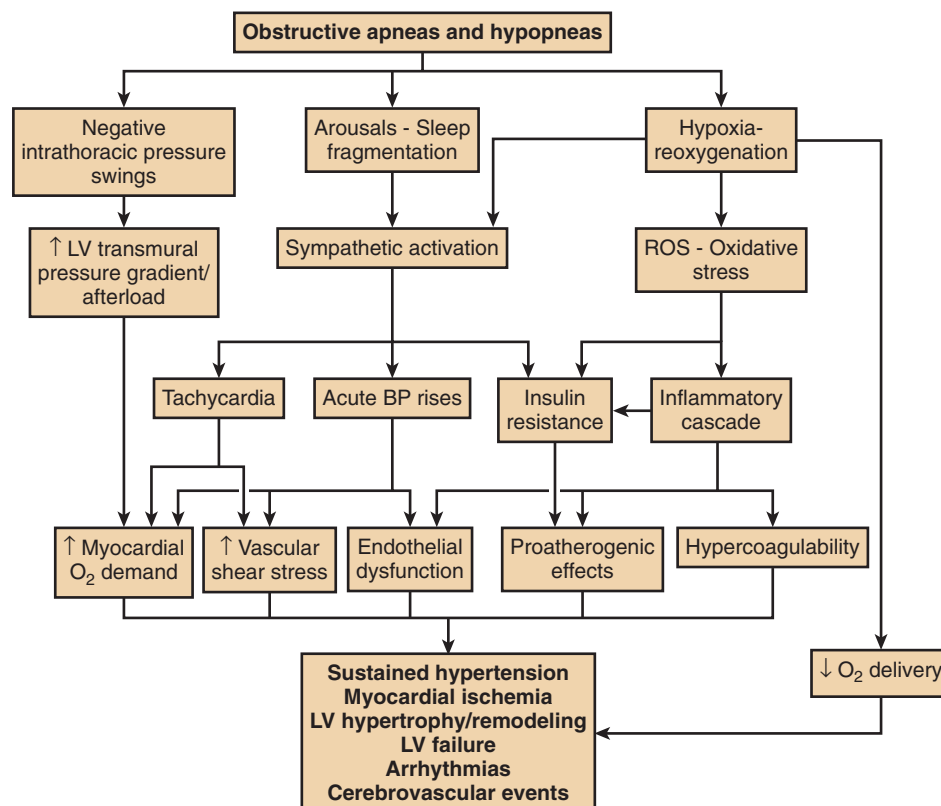

Figure 88-5 Schema indicating mechanisms of cardiometabolic complications of OSA. BP, blood pressure; LV, left ventricular; ROS, reactive oxygen species.

Figure 88-6 Sympathetic nerve activity during obstructive apneas. Tracing demonstrating increased sympathetic nerve activity (SNA) during obstructive apneas together with associated changes in blood pressure (BP) and heart rate. Increase in muscle tone (EMG) and cessation of rapid eye movements (EOG) toward the end of the apneic period indicates arousal from REM sleep (arrows). (Somers VK, Dyken ME, Clary MP, Abboud FM: Sympathetic neural mechanisms in obstructive sleep apnea. *J Clin Invest* 96:1897–1904, 1995.)

wakefulness, contributing to sustained hypertension. OSA-associated hypoxia-reoxygenation has analogous biologic effects to ischemia-reperfusion, leading to generation of reactive oxygen species.¹⁷⁷ This oxidative stress activates nuclear transcription factors, including hypoxia inducible factor-1 α and nuclear factor- κ B, which activate a diversity of proinflammatory pathways.^{177,178} Inflammatory mediators in turn may adversely affect endothelial cell function¹⁷⁹ and promote atherogenesis,¹⁸⁰ have antifibrinolytic/prothrombotic effects that could contribute to acute vascular events, and, in concert with increased sympathetic activity, may increase insulin resistance, further contributing to cardiovascular risk.^{181,182} Animal studies indicate that intermittent hypoxia can also adversely affect lipid metabolism, further contributing to the proatherogenic effects of OSA.¹⁸⁰ There is growing evidence that, on the basis of these pathophysiologic mechanisms, OSA has important clinical effects on cardiovascular morbidity and mortality.

HYPERTENSION

The evidence linking OSA to cardiovascular complications is strongest for hypertension. Experimental studies have shown that repeated airway obstruction during sleep in dogs induces hypertension during wakefulness¹⁸³ and that intermittent hypoxia produces hypertension in rodents.¹⁸⁴ Cross-sectional studies demonstrate an independent association of OSA with hypertension after controlling for obesity,^{185,186} although findings regarding the development of hypertension in longitudinal cohort studies have been discrepant.^{187–189} Recent observational¹⁹⁰ and interventional¹⁹¹ studies reported reductions in hypertension with OSA treatment. The weight of evidence from randomized controlled studies is that *positive airway pressure* (PAP) treatment improves hypertension. Several meta-analyses have been published.^{192–194} In the most recent,¹⁹⁴ PAP was associated with improvements of -2.6 mm Hg (95% CI, -3.6 to -1.6) in systolic and -2.0 mm Hg (95% CI, -2.8 to -1.2) in diurnal blood pressure compared to control, while noctur-

nal values improved by -4.1 mm Hg (95% CI, -6.2 to -1.9) for systolic and -1.90 mm Hg (95% CI, -3.5 to -0.2) diastolic blood pressure. Although these changes appear small, at the population level they could have significant implications for primary cardiovascular prevention.¹⁹⁵ PAP could have additional vascular protective benefits by alleviating the marked surges in blood pressure that accompany OSA.¹⁹⁴ Several studies have reported a high prevalence of OSA (50% to 60%) in patients with refractory hypertension, with OSA representing the most common cause of secondary hypertension in these patients.¹⁹⁶ Two randomized controlled trials have demonstrated significant improvement in blood pressure with PAP treatment in refractory hypertensive patients with OSA.^{197,198}

ARRHYTHMIAS

OSA is associated with cardiac arrhythmias.^{199,200} Bradyarrhythmias, including sinus pauses and atrioventricular block, are more common in severe OSA than in the general population. Although some data suggest that CPAP may improve bradyarrhythmias, there are no randomized trials demonstrating this.¹⁹⁹ Studies linking OSA to ventricular arrhythmias have produced conflicting results.¹⁹⁹ However, there is growing evidence linking OSA to atrial fibrillation.^{199–201} Atrial fibrillation is more common in individuals with severe OSA than in those without OSA.^{199,202} Untreated OSA is associated with a higher rate of recurrent atrial fibrillation after either cardioversion^{203–205} or catheter ablation.^{205,206} Although randomized controlled trials need to be done to confirm an effect of OSA treatment on control of atrial fibrillation, evaluation for OSA and, if present, institution of treatment should be considered in patients with atrial fibrillation.

MYOCARDIAL INFARCTION

OSA has been associated with ischemic heart disease in epidemiologic studies. In the Sleep Heart Health Study there was a modest association of OSA with coronary heart disease (adjusted OR, 1.3 [95% CI, 1.0 to 1.6]).²⁰⁷ In a meta-analysis of four cohort studies, OSA was associated with a risk for coronary disease of 1.9 (95% CI, 1.1 to 3.5) in men,²⁰⁸ although no significant association was observed in the one study of women.²⁰⁹ However, OSA is reported to be prevalent among patients who have suffered acute myocardial infarction²¹⁰ and, if present, OSA is associated with worse cardiovascular outcomes.^{211–213} In observational studies, coronary patients who accepted OSA treatment suffered fewer subsequent cardiovascular events^{214,215} than those who declined.

Similarly, in unselected OSA patients, compliance with OSA treatment has been associated with reduced cardiovascular morbidity and mortality compared to refusal of treatment.²¹⁶ However, refusal of CPAP may be a marker of poor health behavior that could also adversely affect outcomes. Thus, randomized controlled trials are needed. There are currently at least three large clinical trials being conducted to assess the effects of OSA treatment on incident cardiovascular events (*Sleep Apnea Cardiovascular Endpoints* [SAVE],²¹⁷ *Randomized Intervention with CPAP in Coronary Artery Disease and Sleep Apnoea* [RICCDSA],²¹⁸ and CPAP

in Patients With Acute Coronary Syndrome and Obstructive Sleep Apnea²¹⁹). The recently published *Multicentre Obstructive Sleep Apnoea Interventional Cardiovascular (MOSAIC)* trial evaluated the effects of CPAP compared to control on reduction of a surrogate cardiovascular risk score and found that calculated risk was not significantly reduced.²²⁰ However, CPAP was associated with a significant improvement in endothelial function in a subgroup of MOSAIC subjects.²²¹ Follow-up of MOSAIC subjects for long-term “hard” cardiovascular outcomes may yield additional findings. A recent randomized trial by the Spanish collaborative group showed no significant difference over 7 years in the incidence of cardiovascular events and hypertension in CPAP-treated compared to control groups.¹⁹¹ However, there was a significant reduction in events for patients compliant with CPAP for 4 or more hours per night (incidence density ratio, 0.7 [95% CI, 0.5 to 0.9]) compared with control group).

CEREBROVASCULAR EVENTS

Cross-sectional and longitudinal epidemiologic studies show that OSA is associated with stroke.²²²⁻²²⁴ A recent meta-analysis of five studies showed a significant association of OSA with incident stroke (OR, 2.2; 95% CI, 1.6 to 3.2).²⁰⁸ Thus OSA predisposes to stroke, though stroke may also in turn produce or worsen sleep-disordered breathing. However, studies suggest that in many cases OSA preceded the stroke.^{225,226} Overall, OSA is highly prevalent among those with stroke and transient ischemic attacks, with a recent meta-analysis reporting a prevalence of 63% (95% CI, 58% to 68%) for AHI greater than 10 episodes per hour (data from 24 studies).²²⁶ The presence of OSA after stroke appears to confer a worse prognosis for recurrent stroke and poststroke mortality.²²⁷ Treatment of OSA with CPAP in stroke patients may be challenging and, although several studies have suggested that OSA treatment may improve poststroke outcomes, these have methodologic limitations and are not conclusive.²²⁷

CONGESTIVE HEART FAILURE

OSA was found to be associated with congestive heart failure in the Sleep Heart Health Study (OR of 2.4 for the highest category of OSA severity) in the initial cross-sectional analysis²⁰⁷ and with development of new heart failure in longitudinal follow-up.²⁰⁹ OSA has been identified in 11% to 53% of patients with stable chronic congestive heart failure (with central sleep apnea–Cheyne-Stokes respiration also being present in 11% to 35%, yielding an overall apnea prevalence of approximately 50% in congestive heart failure patients).^{175,228} OSA may worsen left ventricular function. Experimentally induced severe OSA in a dog model produced changes in left ventricular dimensions and reduced systolic function after 8 weeks.²²⁹ A recent meta-analysis of six studies evaluating the effects of OSA treatment on left ventricular function showed a significant mean improvement in left ventricular ejection fraction of 5.2% (95% CI, 3.3% to 7.1%).²³⁰ However, randomized controlled trials are required to demonstrate long-term improvement in cardiac function and prognosis with OSA treatment in patients with congestive heart failure.

PULMONARY HYPERTENSION

Pulmonary hypertension (PH) may develop in OSA either secondary to left ventricular hypertrophy and diastolic dysfunction (e.g., in systemic hypertension [postcapillary PH]) or through pulmonary vascular changes related to acute apnea-related hemodynamic changes and hypoxic vasoconstriction^{231,232} (precapillary PH). The prevalence of PH in OSA remains somewhat uncertain. Pooled data from one larger²³³ and several smaller studies totaling 519 OSA subjects yielded a 10% PH prevalence (defined as *mean pulmonary artery pressure* [Ppa] > 25 mm Hg at cardiac catheterization).²²⁸ However, many patients had comorbidities, and the main predictors of PH were daytime PO₂, PCO₂, and reduced lung function.^{233,234} The weight of evidence indicates that the majority of OSA patients without comorbidities have normal Ppa, and PH, when present, is mild.²²⁸ PH can be more severe, but this is almost invariably associated with both underlying lung function abnormalities (*chronic obstructive pulmonary disease* [COPD], obesity restriction, neuromuscular disease) and daytime hypoxemia and hypercapnia.^{228,233-235} Early studies in severe OSA patients showed that Ppa can improve substantially following tracheostomy but may not normalize.^{232,236} There have been few controlled trials assessing the effect of CPAP treatment on PH, though one recent sham-CPAP controlled study showed reductions in echocardiographically determined Ppa systolic pressure from 28.9 ± 8.6 to 24.0 ± 5.8 mm Hg ($P < 0.001$), with the greatest reductions seen in patients with initially elevated Ppa.²³⁷

INSULIN RESISTANCE

There is growing evidence that independent of obesity, OSA is a risk factor for insulin resistance, hyperglycemia, and type 2 diabetes.^{181,182} When one looks at patients with OSA, there appears to be a significantly increased prevalence of insulin resistance and/or hyperglycemia, with prevalence estimates varying from 20% to 67%.^{182,238} In addition, the prevalence of type 2 diabetes in OSA patients is increased compared to those without OSA, with an estimated prevalence of 15% to 30%.¹⁸² When one looks instead at patients with type 2 diabetes, OSA has been found to be highly prevalent, ranging from 58%²³⁹ to 88%.²⁴⁰

A key issue is whether treatment of OSA improves insulin sensitivity and glycemic control. A variety of uncontrolled trials and seven randomized controlled trials involving relatively small sample sizes (reviewed by Pamidi and Tasali¹⁸²) have shown either improvement or no change, so this issue remains unresolved. However, there should be a high level of clinical suspicion for OSA among patients with type 2 diabetes, and treatment of OSA in such patients may have a host of beneficial effects beyond improvement in glucose control.

MORTALITY

In keeping with the links between OSA and cardiometabolic dysfunction, OSA is associated with increased mortality. Most of the increased mortality is cardiovascular and is seen largely in individuals with severe OSA.²⁴¹⁻²⁴⁴ Of note, survival for patients with severe OSA was identical whether

or not patients complained of sleepiness.²⁴¹ This supports the notion that treatment should be offered to nonsleepy patients with OSA.¹⁹¹ Data from two groups suggest that some of the excess mortality in OSA may be related to cancer.^{245,246} Animal studies have shown that intermittent hypoxia and sleep fragmentation may promote tumor growth through vasogenic or other mechanisms.²⁴⁷ However, further research is required to confirm a link between OSA and cancer mortality.

TREATMENT OF OSA

Although there are a growing number of therapeutic options for OSA, the mainstay of treatment for moderate to severe OSA is PAP therapy. However, conservative measures may produce meaningful improvements in some patients with milder OSA, and there is a role for oral appliance therapy and for upper airway surgery in some patients (see Fig. 88-4B).

WEIGHT LOSS AND OTHER CONSERVATIVE TREATMENT

Reductions in weight are associated with an improvement in AHI.^{44,45} Although achieving meaningful sustained weight loss in clinical practice remains challenging, there are three randomized, controlled trials that demonstrate improvements in OSA severity with dietary and/or lifestyle modifications.²⁴⁸⁻²⁵⁰ In one study in patients with type 2 diabetes, diet and lifestyle modification led to a mean reduction of 10.7 kg and 5.5 kg body weight in the intervention group, with a reduction in AHI that was on average 9.7 and 7.7 events per hour greater than control group at 1 and 4 years, respectively.²⁵⁰ At 4 years, OSA had resolved in 21% of the intervention group compared with 3% of the control group. Thus OSA treatment strategies should include a major emphasis on lifestyle modification and weight reduction for obese patients.

There are very few studies addressing the effects of pharmacologic weight-reducing agents on OSA. The addition of sibutramine to diet and lifestyle modification improved OSA,^{251,252} although there are concerns about cardiovascular side effects of this medication. A study in patients with moderate to severe OSA showed that a combination of phentermine and sustained-release topiramate led to significantly greater weight reduction and improvement in AHI (fall of 31.5 versus 16.6 events per hour in controls) at 28 weeks, with few side effects.²⁵³

Bariatric surgery in the morbidly obese can produce dramatic reductions in weight and substantial improvements in OSA.²⁵⁴ A meta-analysis of 12 studies²⁵⁵ found a reduction in mean body mass index from 55.3 to 37.7 kg/m² following bariatric surgery, with a significant fall in mean AHI from 54.7 to 15.8. Of note, however, residual disease requiring treatment (i.e., AHI > 15 events per hour) was still present in 62% of subjects. Thus OSA may be cured following bariatric surgery, but this is not common.

Other conservative measures for management of OSA include avoidance of alcohol or sedatives/muscle relaxants. Up to 50% of OSA patients have a significant positional

component with supine worsening.⁵⁶ For such patients, positioning treatment (tennis balls sewn into a pajama top, dedicated positioning belt, etc.) may be effective. However, this may be poorly tolerated or ineffective in maintaining the supine position, and long-term compliance may be poor.²⁵⁶

ORAL APPLIANCES

The best-studied and most effective intraoral appliances are *mandibular advancement devices* (MADs). These should be custom-made by a dental health professional with specific expertise. Prefabricated (“boil and bite”) MADs are less expensive but less effective. Tongue-retaining devices are also available but less effective.²⁵⁶ MADs compared with placebo improve AHI and daytime sleepiness but are less efficacious in reducing AHI and improving nocturnal arterial SO₂ than PAP.²⁵⁷ Thus MADs are recommended for patients with mild to moderate OSA or for those unable or unwilling to use PAP.²⁵⁸ Patients with severe OSA and/or severe symptoms should have a trial of PAP.^{256,258} A randomized trial of MAD versus CPAP in moderate to severe OSA showed that the MAD was less effective in lowering AHI after 1 month of treatment, but compliance with the MAD was better. The two treatments produced comparable improvements in sleepiness and quality of life.²⁵⁹ Once MADs have been fitted and advanced optimally based on comfort, snoring, and OSA symptoms, a follow-up sleep study should be performed to document effective OSA control.^{256,258}

POSITIVE AIRWAY PRESSURE

PAP therapy in OSA delivers positive pressure to the upper airway via a sealed mask serving as a “pneumatic splint” that distends the airway and prevents collapse during sleep. PAP is highly efficacious and successfully alleviates OSA in a large majority of patients. The standard form of PAP is fixed CPAP, in which a continuous pressure is delivered throughout inspiration and expiration. The conventional, gold-standard approach for determining the effective CPAP level is manual titration during attended PSG (see Fig. 88-6). The effective pressure may vary with body position (higher pressure is usually required in the supine position) and with sleep stage because of greater upper airway muscle atonia during REM. The final pressure prescribed is the lowest level that alleviates respiratory events in all body positions and sleep stages.²⁶⁰

Randomized controlled trials have demonstrated that PAP improves daytime sleepiness and quality of life,^{173,261,262} with the greatest improvements in subjective sleepiness being observed in severe OSA.²⁶¹ However, the *CPAP Apnea Trial North American Program* (CATNAP trial) demonstrated significant improvements in OSA-specific quality of life, sleepiness, and mood with CPAP in patients with mild to moderate OSA.²⁶³ PAP treatment of OSA is associated with a reduced rate of motor vehicle crashes.¹⁵⁰

Improvement in clinical outcomes correlates positively with PAP compliance.²⁶² However, compliance with PAP is challenging for some patients, with long-term estimates varying from 30% to 85%.²⁶⁴ Diverse practical and psychosocial issues need to be considered in optimizing PAP

compliance. Different interfaces are available, including nasal or nasal-oral (full face) masks and intranasal interfaces. Patients may need to try several different masks to optimize seal and comfort. The routine use of in-line heated humidification is recommended to reduce nasal symptoms and improve compliance.²⁶⁵ Educational interventions at CPAP initiation and supportive or cognitive behavioral interventions help improve PAP compliance.²⁶⁴

Compliance can be documented objectively via microprocessors integrated within PAP units. Data on the hours of use, the degree of residual sleep-disordered breathing, and mask leak are available and are generally reliable.²⁶⁶ Objective usage data are more reliable than patients' self-reported compliance. Microprocessor data provide the opportunity to improve compliance through feedback and counseling and to optimize therapy based on objective data (correction of mask leak, pressure adjustment to reduce residual AHI). Adherence early in PAP use is important in predicting long-term use.²⁶⁷ Compliance monitoring and close follow-up after initiation of PAP should be key components of treatment programs.²⁶⁵

Modifications of conventional fixed CPAP pressure profiles have also been developed to improve patient comfort and compliance. *Bilevel PAP* (BPAP) delivers a higher pressure during inspiration and a lower pressure during expiration. This may improve tolerance, particularly in patients with high CPAP requirements.²⁶⁸ For OSA patients who require ventilatory support because of concomitant nocturnal hypoventilation (e.g., due to obesity, COPD, or neuromuscular disease), BPAP both maintains airway patency and provides an increase in inspiratory pressure to augment ventilation.²⁶⁵ Several manufacturers have developed an expiratory pressure reduction option that can be engaged on standard PAP units. Although patient comfort may be improved by pressure profile modification, this does not translate into overall improved compliance.²⁶⁹ Some patients with demonstrated poor compliance may show improved compliance with pressure profile modification.²⁷⁰

PAP devices are now available that continuously self-adjust the pressure to treat OSA based on analysis by an internal microprocessor of flow amplitude reductions, inspiratory flow limitation, and/or snoring.²⁷¹ These are referred to as *auto-PAP* (APAP) or *auto-BPAP*. Although the application of auto-BPAP has been somewhat limited, APAP has assumed a prominent role in the management of OSA. A major advantage of APAP is that OSA patients without major comorbidities can start effective PAP treatment without the requirement for in-laboratory manual titration. In such patients, APAP can be used either to determine a pressure for fixed CPAP after several nights of autotitration, or APAP treatment can be continued long term.²⁷¹ A meta-analysis²⁷² found that CPAP and APAP were equally effective in reducing AHI, although CPAP was slightly superior in improving minimum arterial SO_2 by 1.3% (95% CI, 0.4% to 2.2%) more than APAP. Two meta-analyses^{269,272} found that objective compliance and reduction in Epworth sleepiness score were similar for APAP and CPAP, with a minor, likely clinically insignificant, advantage to APAP. Few studies to date have addressed potential differences in cardiovascular outcomes between CPAP and APAP.

SURGICAL TREATMENT

Surgical procedures that aim to relieve sites of upper airway narrowing have been developed. Overall, the success of surgical treatments for OSA in adults is limited, difficult to predict, and considerably less than with PAP therapy.^{131,256,273} The most commonly applied techniques are aimed at palatal reduction either using conventional surgical methods (uvulopalatopharyngoplasty) or laser-assisted uvulopalatoplasty and radiofrequency-based procedures. Surgeries for nasal and palatal reduction, as well as tongue reduction or tongue advancement surgeries, are referred to as phase 1 surgeries and may be performed in combination ("multilevel surgery") or separately from phase 2 surgeries such as maxillomandibular advancement.

Tracheostomy is an effective treatment for OSA but is recommended only when all other options have been exhausted due to complications and poor patient tolerance.¹³¹ Based on recent reviews,^{256,273} current recommendations are that uvulopalatopharyngoplasty does not reliably normalize AHI in moderate to severe OSA, so that severe OSA patients should be offered PAP and moderate OSA patients should be offered PAP or MAD.¹³¹ Laser-assisted uvulopalatoplasty is not recommended for OSA of any severity, whereas radiofrequency ablation can be considered for mild to moderate OSA patients who are unwilling or unable to tolerate PAP or MAD.¹³¹ The quality of evidence supporting more invasive surgical procedures such as maxillomandibular advancement or multilevel surgery is low, and these procedures are recommended only when alternative treatment approaches have failed.^{131,256} All patients who undergo surgical intervention for OSA should have repeat objective sleep testing after appropriate healing to document OSA resolution.

OTHER TREATMENT APPROACHES

There is currently no definitive pharmacotherapy for OSA.^{274,275} There is limited, short-term evidence that upper airway exercises may be beneficial in mild to moderate OSA, although exercise has to be continued to maintain beneficial effects.²⁵⁶ Expiratory nasal pressure valves (Provent) applied to the nostrils may be effective in mild to moderate²⁷⁶ but not severe OSA.²⁷⁷ Hypoglossal nerve stimulation devices are currently being evaluated for effectiveness in OSA.²⁷⁸⁻²⁸⁰ Although preliminary results are promising, application will likely be limited due to the high cost of neurostimulators. The use of therapies selected on the basis of OSA phenotyping (e.g., oxygen for high loop gain, sedatives to diminish arousal response) is discussed in Chapter 85. To date, however, these approaches have limited practical applicability for moderate to severe OSA.

PERIOPERATIVE CONSIDERATIONS IN OSA

Untreated OSA is associated with an increased risk for perioperative complications.^{281,282} This is related to perioperative administration of sedatives, anesthetics, and opioids,

which increase pharyngeal collapsibility, decrease ventilatory responses to respiratory stimuli, and impair arousal responsiveness.²⁸² In a meta-analysis,²⁸¹ OSA was associated with a significantly increased risk for postoperative cardiac events (OR, 2.1; 95% CI, 1.2 to 3.5), acute respiratory failure (OR, 2.4; 95% CI, 1.3 to 4.4), postoperative desaturation (OR, 2.3; 95% CI, 1.2 to 4.3), intensive care unit transfer (OR, 2.8; 95% CI, 1.5 to 5.4), and a tendency to increased reintubation (OR, 2.1; 95% CI, 0.9 to 4.4). Several societies have made recommendations for evaluation and management of OSA patients in the preoperative, intraoperative, and postoperative periods.²⁸³⁻²⁸⁵ Attention should be paid to preoperative identification of known or high-probability OSA patients. For elective surgery, patients with suspected OSA should undergo diagnostic testing and be established on effective PAP treatment before admission for surgery, with continuation of PAP throughout the hospitalization. Suspected or known OSA patients should be managed perioperatively as “difficult airway” patients, with minimization of opioid use, use of short-acting sedatives/anesthetics, and regional anesthesia when possible. Postoperative monitoring should be performed and PAP applied postoperatively when possible.

DISEASE MANAGEMENT STRATEGIES FOR OSA

Given the high prevalence of OSA and the high costs and limited access in many countries to laboratory PSG,¹⁰⁹ alternate strategies to conventional PSG-based diagnosis and titration in highly specialized centers are needed for management of OSA.^{286,287} Mulgrew and colleagues²⁸⁸ demonstrated that ambulatory-based diagnosis of severe OSA followed by titration using APAP and then treatment with fixed CPAP yielded equivalent clinical outcomes at 3 months compared with a conventional in-laboratory diagnostic and manual titration approach. A series of subsequent publications have supported these findings, with some of the later studies also including more moderate OSA.²⁸⁹⁻²⁹³ All of these studies, however, were conducted in specialty sleep centers and involved traditional interactions between patients and specialized sleep physicians.

Recently Australian investigators evaluated the ability of specialist sleep center nurses to direct algorithm-based ambulatory management of moderate to severe OSA and compared outcomes with traditional PSG and specialist physician-based management. Improvements in Epworth sleepiness scores were noninferior for the nurse-led strategy, and CPAP compliance and other clinical outcomes were also similar.²⁹⁴ This group performed a subsequent study in which the experimental arm was management of OSA by family physicians and community clinic nurse practitioners who had received training from a specialist sleep center.²⁹⁵ The primary care management arm was found to yield noninferior improvement in Epworth scores; CPAP compliance and other clinical outcomes were also similar. Thus ambulatory-based programs for management of moderate to severe OSA in patients without major medical comorbidities are feasible, but need to be conducted within or in close

relationship with specialist sleep centers. A very helpful clinical guideline for OSA diagnosis and management has been published.²⁹⁶

Key Points

- Obstructive sleep apnea (OSA) is a frequent health problem in the general population, estimated to affect approximately 14% of men and 5% of women, with the risk increasing further in women after menopause.
- Pathogenic factors contributing to OSA may differ between individuals and include reduced airway dimensions, sleep-associated decrements in upper airway muscle activity and protective reflexes, changes in upper airway tissue characteristics and neuromuscular function, nocturnal fluid shift, and altered chemosensitivity and arousal responsiveness.
- OSA is associated with daytime sleepiness and increased motor vehicle accidents and may adversely affect cognitive function, mood, and quality of life.
- There is evidence linking OSA to hypertension, arrhythmias, vascular ischemic events, congestive heart failure, pulmonary hypertension, and increased mortality.
- Diagnosis of OSA syndrome rests on both clinical history and a diagnostic sleep recording documenting the presence of obstructive events during sleep.
- The standard of care for moderate to severe OSA is treatment with *positive airway pressure* (PAP). Mandibular advancement devices or surgical intervention may be useful in selected patients.
- OSA is associated with an increased risk for perioperative complications. OSA treatment should be started before elective surgery when possible; patients with known or suspected untreated OSA undergoing emergency surgery should be monitored closely in the postoperative period.
- Technologic advances in diagnostic recording and self-adjusting (auto-PAP) machines have made ambulatory management feasible for OSA patients without major comorbidities.

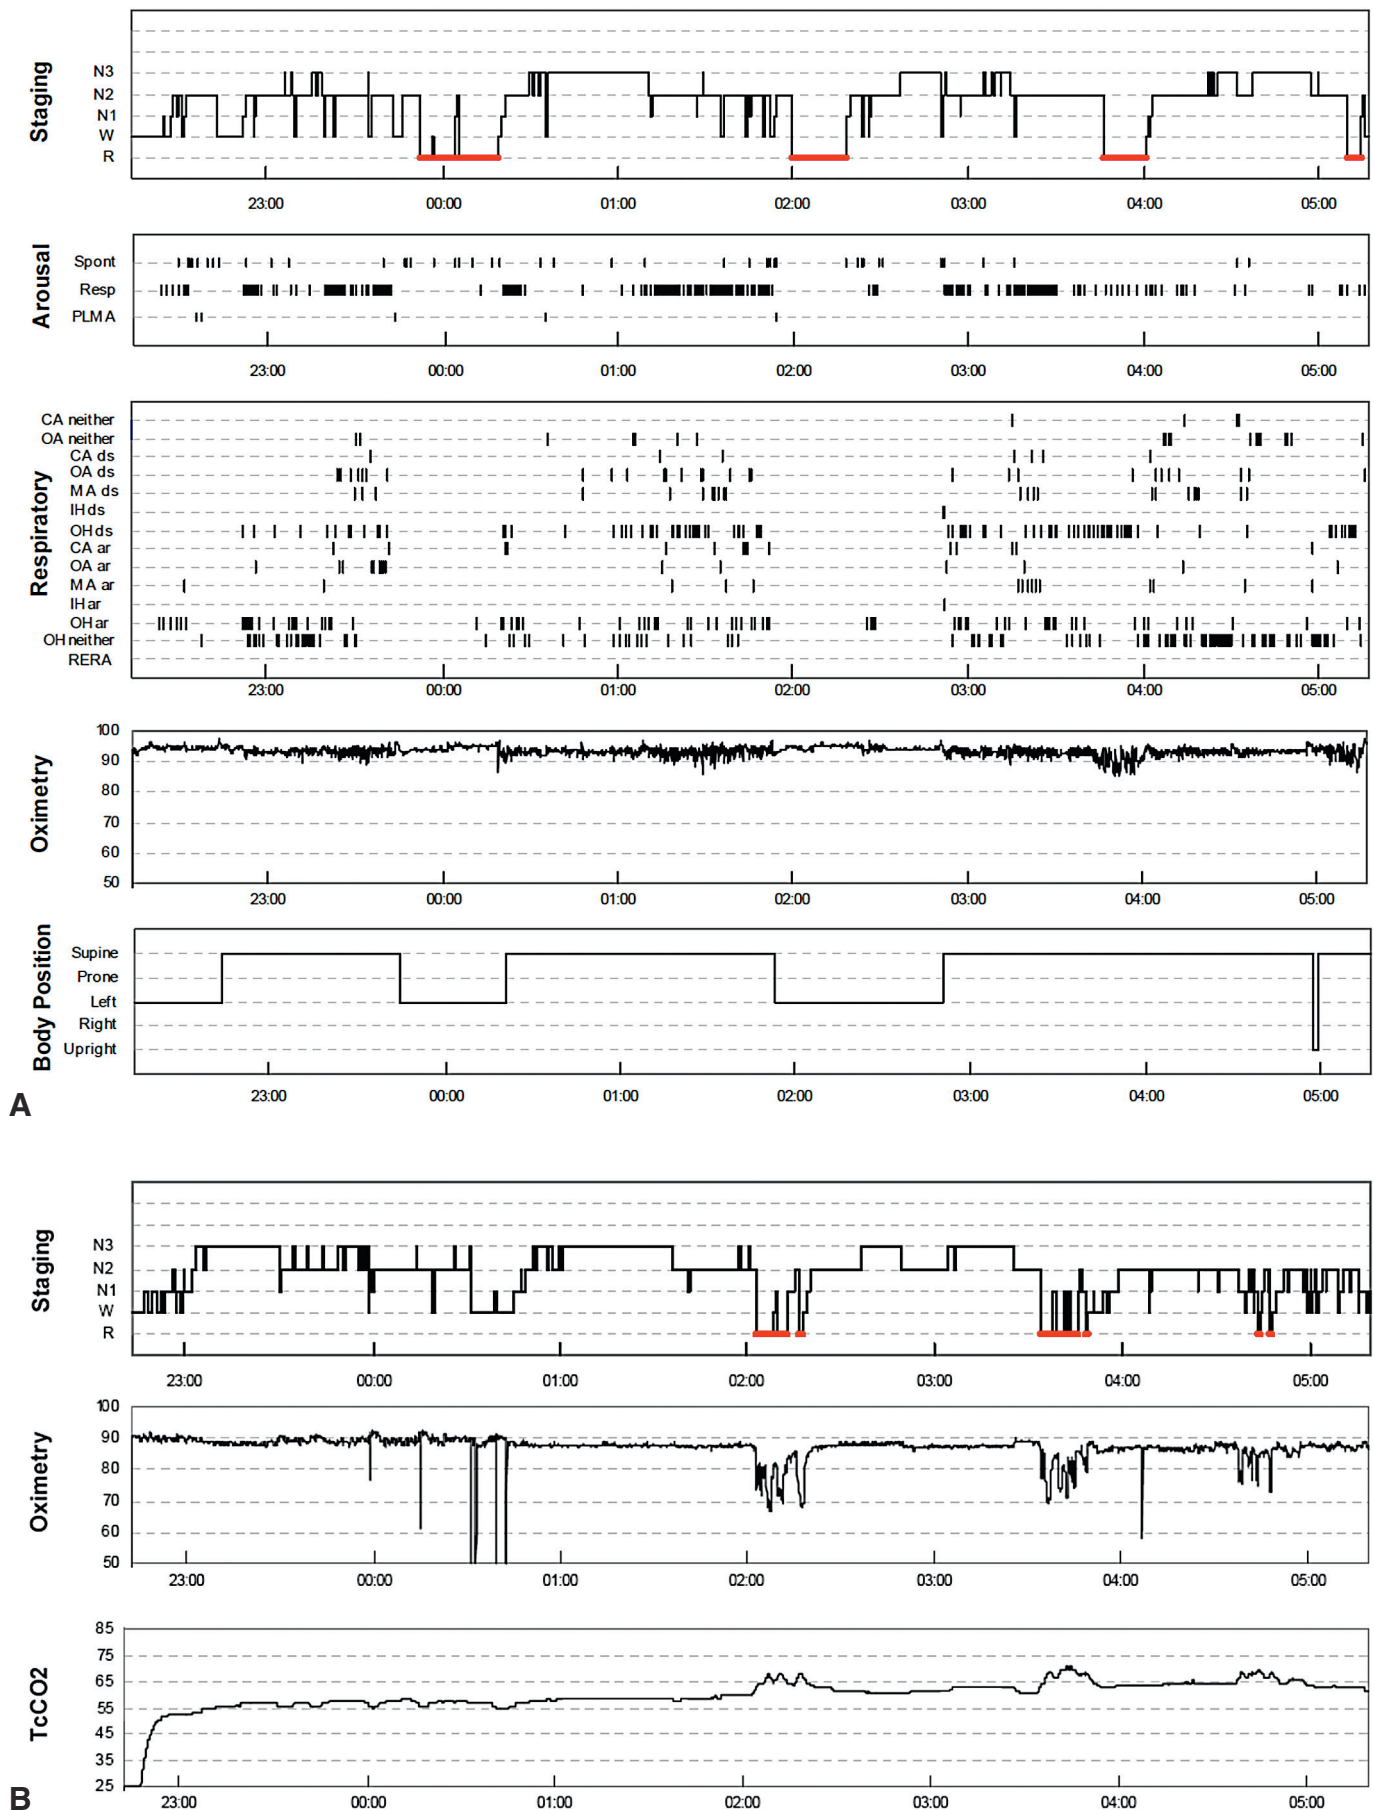

Figure 88-1 Composite hypnograms generated by sleep analysis software after manual scoring by a technologist of sleep-wake stages and respiratory events. A, Typical report from a patient with OSA. In this patient, apneas and hypopneas happen predominantly when the patient is sleeping supine; oxygen desaturation is more marked for events in supine stage R (REM sleep) (red bar) than in stages N (non-REM), which is often the case. **B,** Sleep-associated hypoventilation, with a progressive rise in transcutaneous carbon dioxide (TcCO₂) over the night from an initial value of 54 mm Hg to a peak of 72 mm Hg, with an absence of apneas or hypopneas. There is worsening of hypoventilation during periods of stage R (REM sleep) (red bar), when arterial SO₂ falls and carbon dioxide rises markedly.

**A****B**

Figure 88-2 Summary data (A) and data tracings (B, apneas shown with red arrows) from a portable type 3 sleep recording performed in a patient's home, demonstrating severe OSA.

INTRODUCTION DIAGNOSIS OF CENTRAL SLEEP APNEA

CLASSIFICATION OF CENTRAL SLEEP APNEA Hypercapnic Central Sleep Apnea

Nonhypercapnic Central Sleep Apnea

INTRODUCTION

A *central sleep apnea* (CSA) results from a transient abolition of central respiratory drive to the respiratory muscles leading to cessation of airflow; this is most often due to a fall in arterial PCO_2 below the threshold required to stimulate breathing. By convention, in adults, apnea is defined as an absence or reduction of airflow to less than 90% of the baseline level for at least 10 seconds. During a central apnea, there is no respiratory effort and therefore no movement of the chest wall; this is in contrast to obstructive apneas, during which central drive and respiratory efforts continue. Hypopneas can also be part of a CSA disorder. In this case, airflow and tidal volume decrease by 50% to 90% compared with normal breathing for at least 10 seconds usually in association with oxygen desaturation or an arousal from sleep, but without evidence of airflow limitation due to upper airway obstruction. Distinguishing central from obstructive hypopneas can be difficult depending on the type of instrumentation used to detect them (see later for more details).

A CSA disorder is defined as recurrent central apneas and hypopneas during sleep. However, a clear threshold above which a CSA disorder can be said to exist has not been well defined owing to its relative rarity and its heterogeneous pathophysiology, clinical symptoms, and complications. Nevertheless, the following criteria—albeit rather arbitrary—have been proposed to define a CSA disorder: an *apnea-hypopnea index* (AHI) of 5 to 15 (mild), 15 to 30 (moderate), or greater than 30 (severe), of which the majority of events are central. Similarly, criteria for a CSA syndrome have not been clearly defined but include the presence of a CSA disorder accompanied by symptoms, which could include habitual snoring, restless sleep, nocturnal awakenings, morning headaches, insomnia, or excessive daytime sleepiness (Table 89-1).^{1,2}

DIAGNOSIS OF CENTRAL SLEEP APNEA

Full overnight polysomnography with instrumentation capable of detecting respiratory effort and airflow limitation is required to diagnose CSA.^{3,4} Respiratory effort is best determined noninvasively by respiratory inductance plethysmography.⁵⁻⁸ Techniques such as piezo-electric crystal bands, oronasal thermistors, and measurement of nasal pressure are not reliable in ruling out respiratory

efforts and therefore of distinguishing central from obstructive events.⁹⁻¹¹ Most laboratories do not differentiate hypopneas as being central or obstructive, which is a problem because in patients with OSA or CSA, most respiratory events are hypopneas. Thus, in many cases, the classification of the type of sleep apnea disorder is made on the basis of apneas, which constitute a minority of respiratory events. Central hypopneas are characterized by attenuated in-phase thoraco-abdominal motion due to reduced respiratory drive and in the absence of airflow limitation due to upper airway obstruction.³ In some cases, more sensitive techniques may be required to detect the presence of respiratory effort or airflow limitation, such as measurement of esophageal pressure or diaphragm electromyographic activity.^{8,12} The use of oxygen desaturation criteria for hypopneas is controversial because central events in patients with heart failure are accompanied by less oxygen desaturation than obstructive events of similar duration,¹³ and it is unclear to what extent oxygen desaturation contributes to morbidity or mortality.¹⁴

CLASSIFICATION OF CENTRAL SLEEP APNEA

CSA is not a single disease entity but rather includes several heterogeneous disorders as outlined in Table 89-2. Nevertheless, common to all forms of CSA is that arterial PCO_2 comes to lie below the level required to stimulate breathing during sleep (i.e., the apnea threshold). The PCO_2 can be lower than the apnea threshold because of either a decrease in PCO_2 or an increase in the apnea threshold. A CSA caused by an increase in the apnea threshold with onset of sleep is illustrated in Figure 89-1. On the basis of theoretical, experimental, and clinical considerations, two distinct underlying mechanisms can account for cessation of central respiratory output during sleep.

First, outright defects in the respiratory control system or in the respiratory neuromuscular apparatus can lead to central apneas. Such defects generally result in suppressed respiratory drive, manifested by some degree of daytime hypercapnia. However, the full impact of such defects becomes most apparent during sleep, when nonchemical waking neural drive to breathing is abolished, and the stimulatory influence of behavioral, cortical, and reticular inputs to the brain stem respiratory neurons are reduced. In this situation, breathing becomes critically dependent on the defective metabolic respiratory control system, resulting

Table 89-1 Clinical Characteristics of Patients with Central Sleep Apnea

Characteristic	Hypercapnic	Nonhypercapnic
Sex distribution	Equal	Predominantly male
History of respiratory failure	Frequent	Not reported
Peripheral edema and cor pulmonale	Frequent	Not reported
Polycythemia	Frequent	Not reported
Muscle weakness	Frequent	Not reported
Morning headaches	Common	Uncommon
Snoring	Common	Frequent
Nasal obstruction	Uncommon	Common
Hypertension	Uncommon	Common
Nocturnal choking	Uncommon	Common
Nocturnal awakenings and insomnia	Uncommon	Common
Daytime sleepiness	Frequent	Frequent
Restless sleep	Common	Common

Table 89-2 Classification of Central Sleep Apnea

Hypercapnic ($\text{PCO}_2 > 45$) (Decreased respiratory drive)	Central alveolar hypoventilation Secondary Brain stem tumors, infarcts Bulbar polio Encephalitis Primary Respiratory neuromyopathy Neuromyopathies Myotonic dystrophy Muscular dystrophy Myasthenia gravis Amyotrophic lateral sclerosis Postpolio syndrome Diaphragm paralysis
Nonhypercapnic ($\text{PCO}_2 \leq 45$) (Normal or increased respiratory drive)	Secondary Congestive heart failure (Cheyne-Stokes respiration) Brain lesions Renal failure Acromegaly Cerebrovascular disease Atrial fibrillation High-altitude periodic breathing Opioid related Complex sleep apnea Primary Idiopathic central sleep apnea

in more pronounced hypercapnia during sleep than during wakefulness.^{15,16} In this case, central apnea is triggered by a fall in PCO_2 below the apnea threshold but in conjunction with a markedly elevated PCO_2 apneic threshold. **Figure 89-2** illustrates a typical central apnea in a patient with hypercapnic CSA: As respiratory drive diminishes during sleep, there is a gradual reduction in tidal volume until breathing stops.

Second, transient fluctuations or instabilities in an otherwise intact respiratory control system can lead to central apneas. These instabilities typically arise during drowsiness and during light, *non-rapid eye movement* (non-REM) sleep

Figure 89-1 Schematic diagram showing a proposed mechanism underlying central sleep apnea at sleep onset. With the loss of the waking neural drive to breathing at sleep onset, there is an increase in the apnea threshold (black line labeled Threshold), the arterial PCO_2 (PaCO_2) required to maintain respiratory rhythm. As a result, the arterial PCO_2 (blue line labeled Arterial) that was present during wakefulness may now be below the threshold arterial PCO_2 for rhythm generation in sleep. Hence, ventilation (\dot{V}) falls to zero and apnea ensues until arterial PCO_2 rises above the threshold level for rhythm generation in sleep, whereupon rhythmic breathing resumes. non-REM, non-rapid eye movement. (From Bradley TD, Phillipson EA: Central sleep apnea. *Clin Chest Med* 13:493–505, 1992.)

and, because there is no suppression of respiratory drive, arterial PCO_2 levels during wakefulness or sleep are normal or low. This type of CSA is typically triggered by a sudden increase in ventilation that causes PCO_2 to fall below the apnea threshold, often due to an arousal from sleep as illustrated in the upper panel of **Figure 89-3**. This type of CSA is characteristically associated with periodic breathing, during which there are regularly recurring alterations in tidal volume between central apneas/hypopneas and hyperpneas. Several theoretical and experimental models have been developed to account for such transient fluctuations in central respiratory drive. Common to all these models is a PCO_2 level during sleep that falls transiently close to (hypopnea) or below (apnea) the critical threshold value required for maintenance of regular respiratory rhythm.

Such transient discrepancies in PCO_2 levels arise in a number of conditions, the most common of which is the transition from wakefulness to sleep. Because of the waking neural drive to breathe, ventilation is higher and PCO_2 levels are lower during wakefulness than during sleep.¹⁶ Withdrawal of this drive at the transition from wakefulness to sleep results in a PCO_2 level that, although appropriate for wakefulness, is below the value appropriate for sleep (see **Fig. 89-1**). If this PCO_2 level of wakefulness is below the threshold value for rhythm generation during sleep, apnea will ensue at sleep onset until PCO_2 rises to the critical threshold value when ventilation will resume. If sleep becomes firmly established at this point, regular breathing

Figure 89-2 Hypercapnic central sleep apnea. Polysomnographic recording of central apnea obtained from a patient with hypercapnic central sleep apnea due to primary central alveolar hypoventilation syndrome. Note the typical gradual reduction in tidal volume just before the onset of the central apnea (arrow) and severe degree of hypoxemia with arterial oxygen saturation (SaO₂) below 80% throughout the recording. ECG, electrocardiogram; EEG, electroencephalogram; EMG, electromyogram.

resumes without further apneas or hypopneas. However, in some individuals prone to periodic breathing, the transition from wakefulness to sleep is characterized by repeated fluctuations in central nervous system state between “awake” and “asleep.” With each momentary arousal from sleep toward wakefulness, the PCO₂ levels that were present during sleep represent a hypercapnic stimulus during wakefulness, and ventilation therefore increases in accordance with the awake response to carbon dioxide, resulting in a hyperpneic phase during which there is ventilatory overshoot causing PCO₂ to fall below the apnea threshold on the transition to sleep. In this scheme, the magnitude of fluctuation in ventilation with changes in central nervous system state depends on the difference between the awake and sleeping values of PCO₂ and the steepness of the ventilatory response to carbon dioxide during wakefulness.¹⁷ Any factor that magnifies these variables enhances the tendency to periodic breathing and CSA.

HYPERCAPNIC CENTRAL SLEEP APNEA

The automatic process of breathing originates from the central respiratory rhythm generator located in the pons and medulla. This central generator provides most of the input to spinal motoneurons responsible for activation of respiratory muscles. Hypercapnic CSA results from processes that damage the cerebral cortex, brain stem, spinal cord, muscles, or motor nerves. CSA with hypercapnia almost always presents as chronic respiratory failure with hypercapnia both during wakefulness and sleep due mainly to a reduction in central respiratory drive. At the transition from wakefulness to sleep, the already reduced central drive is further reduced, causing a gradual reduction in ventilation until there is complete cessation of respiratory drive that leads to transient central apneas (see Fig. 89-2). Coincident with this reduction in ventilation, PCO₂ rises and

arterial SO₂ falls. In contrast to nonhypercapnic CSA, apneas and hypopneas are more frequent during REM sleep than non-REM sleep owing to a further reduction in ventilator drive and partial paralysis of the respiratory muscles in REM sleep.¹⁸

Secondary Forms of Hypercapnic Central Sleep Apnea

Developmental and Degenerative Diseases. The brain stem includes the medulla, midbrain, and pons. Although the central respiratory controller is located predominantly in the medulla, it has projections to other areas of the brain stem. Diseases affecting the brain stem, such as tumors, stroke, Chiari malformations, and neurodegenerative diseases, may induce hypoventilation and CSA via a number of mechanisms such as (1) physical compression of the brain stem resulting in damage to the respiratory center and reticular activating system, (2) stretching of the lower cranial nerves and damage to the peripheral chemoreceptors that carry inputs from the carotid bodies to the medulla, (3) depletion of medullary chemosensitive respiratory neurons,¹⁹ or (4) degeneration of the central pattern generator located in the dorsolateral pons.

Chiari malformations are congenital abnormalities of the craniocervical junction with downward displacement of the cerebellar structures often in association with syringomyelia, myelomeningocele, hydrocephalus, and aqueductal stenosis. Chiari malformations are classified into three types. Chiari malformation type I is characterized by abnormally shaped cerebellar tonsils with herniation below the foramen magnum that is associated with the Klippel-Feil anomaly and spinal cavitations. Type II is characterized by the downward displacement of the cerebellar vermis and tonsils below the foramen magnum with associated obstruction of cerebrospinal fluid flow and hydrocephalus, in addition to a myelomeningocele. Type III is downward

Figure 89-3 Nonhypercapnic central apnea. Upper panel: Polysomnographic recording obtained from a patient with nonhypercapnic central sleep apnea due to idiopathic central sleep apnea (ICSA). Note that in contrast to the central apnea shown in Figure 89-2, central apnea in this case follows an abrupt increase in ventilation (arrow) triggered by an arousal, after which there is an abrupt decrease in ventilation to zero. In addition, note that in contrast to the recording shown in Figure 89-2, arterial oxygen saturation (SaO₂) is within normal limits. **Lower panel:** Compressed records of nocturnal arterial SO₂ and transcutaneous PCO₂ (PtCCO₂) in a patient with ICSA (A) and in a patient with obstructive sleep apnea (B). Record reads from right to left. Note that in patient A, the segments containing recurrent apneas (indicated by oscillations in SaO₂) are preceded by a small decrease in PtCCO₂. In contrast, in patient B the segment containing recurrent apneas is accompanied by a small increase in PtCCO₂. Note also that in the PtCCO₂ scales, an upward deflection of the signal indicates a fall in PtCCO₂ and vice versa. ECG, electrocardiogram; EEG, electroencephalogram; EMG_{at}, anterior tibialis electromyogram; EMG_{sm}, submental electromyogram; EOG, electrooculogram. (Upper panel from Xie A, Wong B, Phillipson EA, et al: Interaction of hyperventilation and arousal in the pathogenesis of idiopathic central sleep apnea. *Am J Respir Crit Care Med* 150:489–495, 1994; Lower panel, Bradley TD, Phillipson EA: Central sleep apnea. *Clin Chest Med* 13:493–505, 1992.)

displacement of the medulla with an occipital or cervical encephalocele. These anatomic abnormalities can lead to degeneration of brain stem respiratory neurons with resulting hypoventilation and, in some cases, CSA.

In those with type I Chiari malformation, a prospective study in children showed a prevalence of CSA of 9%, with an increased risk of CSA in those with hydrocephalus.²⁰ In adults with Chiari malformations (types I and II), CSA prevalence was reported to be 15%.²¹ In a small cross-sectional study of patients with Chiari malformation type II and associated myelomeningocele, the prevalence of CSA was much higher: 63%.²²

Congenital central hypoventilation syndrome (CCHS) is a rare genetic disease with an incidence of approximately 1 in 200,000 live births, caused by a mutation of the *PHOX2B* gene.^{23–25} The majority of cases present in the neonatal period or in early childhood with acute or chronic respiratory failure as a result of a loss of respiratory drive. However, it may present de novo in adults following a severe

respiratory infection with combined central and obstructive sleep apnea (OSA).^{26,27} A diagnosis is considered only in those in whom metabolic, neurologic, pulmonary, and medication-induced disorders have been excluded. When CCHS is suspected, the *PHOX2B* screening test is recommended for purposes of genetic counseling.^{28,29}

Neurodegenerative diseases of the brain stem including multiple system atrophy, Leigh syndrome, and Parkinson disease can be accompanied by CSA.^{30–32} Prevalence rates vary depending on the severity of the disease. In one study, 80% of subjects had sleep apnea, of whom 20% had CSA.³³ In patients with multiple sclerosis, a demyelinating disease that can affect both the brain stem and spinal cord, CSA may develop in those with medullary lesions affecting the respiratory neurons.³⁴ The prevalence of CSA in such patients is, however, unknown.

Tumors. There have been fewer than a dozen documented cases of CSA associated with brain stem tumors, suggesting

that tumors are a rare cause of hypoventilation with CSA.³⁵⁻⁴¹ Tumors such as gliomas, meningiomas, astrocytomas, or neurofibromas have been implicated. The tumor type is probably less important than its location, which usually involves the medulla or pons. In a retrospective 8-year series of children with brain stem tumors referred for assessment to a sleep clinic, CSA was found in 14% (2 out of 14).³⁷

Cerebrovascular Disease. CSA can also result from stroke. The stroke location associated with hypercapnic CSA is usually the nucleus tractus solitarius region of the medulla responsible for neural output to the diaphragm.⁴²⁻⁴⁵ Prevalence is probably low because there are only a small number of cases reported in the literature. Interestingly, in Fabry disease, an X-linked recessive multisystem disease characterized by vasculopathic changes and ischemia, CSA was reported in 22% of those with white matter lesions in the brain stem.⁴⁶

Neuromuscular Diseases. Muscular dystrophies, myotonic dystrophy, and other types of inherited and acquired myopathies may result in hypoventilation and hypercapnic CSA. These diseases impair inspiratory muscle function including the diaphragm, leading to alveolar hypoventilation. At the transition from wakefulness to sleep, the associated reduction in ventilatory response to carbon dioxide and hypoxia, combined with the loss of respiratory muscle tone can lead to apneas without respiratory effort (i.e., CSA).^{18,47} Although some central output to the respiratory muscles may be present, and therefore, strictly speaking, events may not be central in origin, the muscles are unable to respond, so there is either markedly reduced or no muscle force generation. The resulting hypopneas and apneas have the appearance of central events. From the clinical viewpoint, it is reasonable to classify these as hypercapnic CSA because their treatment is similar to that for CSA arising from an absence of central drive.

Many of these disorders present in childhood. Although phenotypically variable, most individuals develop progressive muscular weakness and hypoventilation over time. In addition to the high prevalence of hypoventilation, between 20% and 60% of both adults and children develop CSA.⁴⁸⁻⁵⁰ When there is associated cardiomyopathy and heart failure, nonhypercapnic *Cheyne-Stokes respiration* (CSR)—CSA may also be seen in myotonic dystrophy or Duchenne muscular dystrophy.^{51,52}

Diseases of the motor neurons include amyotrophic lateral sclerosis, spinal muscular atrophy, and postpolio syndrome. With degeneration of the respiratory motor neurons, there can be hypoventilation and CSA. The prevalence of CSA is reported to be approximately 18% in amyotrophic lateral sclerosis⁵³ and approximately 5% in postpolio syndrome.⁵⁴

Myasthenia gravis is a disease of the postsynaptic neuromuscular junction. The reported prevalence of CSA in myasthenia gravis is highly variable (0% to 35%) and is probably dependent on disease severity.^{49,55,56}

Primary Hypercapnic Central Sleep Apnea

Primary Central Alveolar Hypoventilation Syndrome. This rare syndrome presents as chronic hypercapnic respiratory failure with normal respiratory mechanics, chest

wall configuration, and muscle strength in the absence of any of the previously mentioned secondary causes. The primary abnormality giving rise to hypoventilation is reduced sensitivity of the central and peripheral chemoreceptors.⁵⁷ In some cases, this may be due to CCHS.⁵⁸ There have only been a few cases of CSA described in association with primary central alveolar hypoventilation syndrome.^{18,59} This diagnosis is made only following the exclusion of other causes of CSA and hypoventilation syndromes, including CCHS.

Clinical Features

As indicated in Table 89-1, patients with hypercapnic CSA characteristically present with a clinical picture dominated by symptoms and sequelae of chronic respiratory failure with hypercapnia and hypoxemia that can include cyanosis, polycythemia, peripheral edema, and cor pulmonale.² Patients may present at variable time points following the onset of the underlying disease. Symptoms suggestive of CSA may include snoring, restless sleep, morning headaches, excessive daytime sleepiness, and fatigue. However, some patients with hypercapnic CSA may not have symptoms suggestive of a sleep apnea syndrome.²

Treatment

The initial approach to treatment of hypercapnic CSA is to determine the underlying cause. In some cases, treatment and/or correction of the underlying etiology will alleviate the CSA. For example, in those with tumors compressing the pons or medulla, resection may abolish CSA.⁶⁰ Surgical treatment of Chiari II malformations is dependent on the severity of the malformation, and despite posterior fossa decompression for the Chiari II malformation, CSA will often persist.²² In acute stroke patients, no specific intervention is usually required for CSA because recovery may accompany improvement from the stroke. However, if respiratory failure and CSA persist, specific therapy for these conditions may be indicated as described later. For those with neuromuscular disease, pharmacologic therapies available for some inherited myopathies or myasthenia gravis may also alleviate CSA by improving muscle strength.⁶¹

In most patients the management of CSA is the same as for chronic alveolar hypoventilation syndromes. However, few studies have specifically addressed the treatment of hypercapnic CSA. The main aim of treatment is to augment ventilation and thereby improve gas exchange and abolish CSA.

It is important that patients be cautioned against the use of sedative medications that can induce acute respiratory failure and aggravate CSA. In patients with CSA in association with central alveolar hypoventilation, a trial of the respiratory stimulant, medroxyprogesterone, can be tried but is usually successful in only a minority of patients.⁶² Supplemental nocturnal oxygen may alleviate hypoxia and CSA and may even lower PCO₂ if hypoxia is a cause of central nervous system depression.^{57,59} However, supplemental oxygen can also abolish hypoxic respiratory drive and worsen CSA. Therefore, a trial of supplemental oxygen should be accompanied by careful monitoring of PCO₂ and either Po₂ or arterial SO₂.

Where pharmacologic therapies are unavailable or ineffective, noninvasive ventilation is often indicated, either via

bilevel positive airway pressure support ventilation (BiPAP) or volume-cycled ventilators.⁶³ The aim of noninvasive ventilation is to reduce PCO_2 below 45 mm Hg while awake and below 50 mm Hg while asleep while maintaining arterial SO_2 greater than or equal to 90%. This is best achieved by performing polysomnography during a trial of noninvasive ventilation in which transcutaneous PCO_2 or fraction of end-tidal CO_2 and arterial SO_2 are monitored. It is sometimes possible to maintain normal gas exchange during both sleep and wakefulness through noninvasive ventilation only during sleep. If the underlying disease progresses despite the previously mentioned measures, tracheotomy and invasive mechanical ventilation may be required. Unfortunately, there are no randomized trials or long-term observational studies that have determined the effects of noninvasive and invasive mechanical ventilation on morbidity, mortality, and quality of life in patients with hypercapnic CSA.

NONHYPERCAPNIC CENTRAL SLEEP APNEA

The clinical picture of nonhypercapnic CSA differs in many ways from that of hypercapnic CSA (see Table 89-1). This table is based mainly on symptoms related to idiopathic CSA. Nevertheless, symptoms related to the many secondary forms of nonhypercapnic CSA are, in general, similar.

Secondary Forms of Nonhypercapnic Central Sleep Apnea

Central Sleep Apnea in Association with Heart Failure—Cheyne-Stokes Respiration. An expanded discussion of the pathophysiology of respiratory dysfunction in CSR-CSA is available online at ExpertConsult.

CSA in heart failure is manifest by a Cheyne-Stokes respiratory pattern that can exist during both sleep and wakefulness. Because this chapter focuses on central apnea during sleep, we discuss Cheyne-Stokes respiration with central apneas during sleep and refer to it as CSR-CSA (see also Chapter 85). CSR-CSA is distinguished from other forms of CSA and periodic breathing by its characteristic crescendo-decrescendo pattern of tidal volume in which hyperpneas are markedly prolonged compared with those without heart failure owing to reduced cardiac output and prolonged lung to chemoreceptor circulation time (upper panel of Fig. 89-4). Therefore, a finding of CSR-CSA on a polysomnogram is highly suggestive of low cardiac output and the presence of cardiac dysfunction.

Mechanisms that mediate CSR-CSA remain incompletely understood. However, as in all other forms of nonhypercapnic CSA, central to the process is respiratory control instability resulting from the dependence of the sleep state on metabolic control of ventilation, especially PCO_2 .² A proposed pathophysiologic scheme for CSR-CSA is illustrated in Figure 89-5.

In heart failure, a key factor destabilizing the respiratory control system and predisposing to CSR-CSA is the presence of chronic hyperventilation that lowers arterial PCO_2 both during wakefulness and sleep and maintains it close to the apnea threshold. Because arterial PCO_2 is closer to the apnea threshold than normal, small perturbations, such as arousals from sleep that augment ventilation, may be sufficient to drive arterial PCO_2 below the apnea threshold and trigger

central apneas. The main factor contributing to this instability and hyperventilation is increased loop gain. *Loop gain* is an engineering term first used in the context of sleep-disordered breathing in a mathematical model developed to explain factors involved in the instability within the respiratory control system in patients with CSR-CSA.⁶⁴ Simply put, it is the ratio of ventilatory output to a given stimulus. Ventilation becomes unstable when loop gain is elevated so that the ventilatory output for a given stimulus is higher than normal. So, for example, if central sensitivity to carbon dioxide is augmented, any given increase in PCO_2 will cause a greater than normal increase in ventilation that can then drive PCO_2 close to, or below, the apnea threshold.

It appears that low cardiac output and prolonged circulation time are not crucial to the pathogenesis of the central apneas because there is evidence that cardiac output in heart failure patients with CSR-CSA does not differ significantly from that in heart failure patients without CSR-CSA.⁷⁴ Moreover, in dogs, prolongation of lung-to-carotid body circulation time only precipitated period breathing in a minority of experiments and then only when circulation times approached 1 minute or longer, a time far exceeding that observed in human heart failure.⁷⁵ However, these factors play a role in sculpting the crescendo-decrescendo pattern of hyperpnea because the rate of rise of tidal volume and the duration of the hyperpnea are directly proportional to lung to chemoreceptor circulation time and indirectly proportional to cardiac output.⁷⁶ As a consequence, in patients with heart failure, cardiac output is lower and lung-to-chemoreceptor circulation time, hyperpnea, and periodic breathing cycle duration of CSR-CSA are longer than they are in CSA in patients without heart failure (see Fig. 89-4).⁷⁶

Heart failure is a prevalent condition affecting approximately 1.5% of the general population.⁷⁷ Among patients with symptomatic heart failure, earlier studies involving only men reported a prevalence of CSR-CSA of approximately 40%.⁷⁸ However, more recent epidemiologic studies involving both men and women with heart failure have shown a substantially lower prevalence of CSR-CSA of 15% to 26%,⁷⁹⁻⁸² probably because CSR-CSA is uncommon in women. CSR-CSA also appears to be common in patients with asymptomatic left ventricular systolic dysfunction.⁸³ Risk factors for CSR-CSA include older age (>60), male sex, atrial fibrillation, awake hypoxemia ($PCO_2 \leq 38$ mm Hg), diuretic use, more severe heart failure defined by lower left ventricular ejection fraction, higher New York Heart Association class, higher brain natriuretic peptide level, higher pulmonary capillary wedge pressure,⁶⁶ and higher left ventricular end-diastolic volume.^{78-80,82,84}

OSA and CSA can coexist in patients with heart failure. In a significant minority of patients, there may be a shift between the two types of apnea overnight or over longer periods.^{74,85-87} The shift from predominantly obstructive to central events is associated with reductions in the PCO_2 and prolongation of circulation time and the hyperpnea phase.^{86,87} This suggests a deterioration in cardiac output and elevation in left ventricular filling pressure as a result of the adverse hemodynamic effects of OSA.⁸⁸ Conversely, the shift from central to OSA is associated with improvements in left ventricular ejection fraction and shortening of circulation time.⁸⁵ These observations suggest

Although a detailed discussion of loop gain is beyond the scope of this chapter, several factors interact to increase the tendency to respiratory instability and hyperventilation: (1) increased peripheral and central chemoresponsiveness⁶⁵; (2) elevated pulmonary capillary wedge pressure that causes pulmonary congestion and activation of the pulmonary juxta-capillary irritant receptors that augment central drive and ventilation⁶⁶; (3) impaired cerebral vascular reactivity and blood flow responses to changes in the arterial PCO_2 , leading to instability of breathing.⁶⁷⁻⁶⁹ Whereas this has been proposed as a mechanism for ventilatory instability, it requires a differential effect of PCO_2 on the cerebral arterial and venous vessels that has not been fully demonstrated or explained. Consequently, this potential mechanism remains controversial and not fully established; (4) sleep state instability in which arousals from sleep during the hyperpneic phase of CSR-CSA cause a transient awakening with an associated engagement of the wakefulness drive to breathe, increased chemosensitivity, and a lower arterial PCO_2 apnea threshold.^{70,71} Unlike in OSA, in which arousals happen at apnea termination and contribute to airway opening and resumption of airflow, arousals following central apnea generally develop several seconds after resumption of airflow but before the peak of hyperventilation.⁷² Thus they appear not to have the same protective role as they do in OSA. Indeed, recurrent arousals during the ventilatory phase have been shown to trigger and propagate CSR-CSA.^{70,73}

CSR-CSA is typically seen during non-REM sleep and resolves or becomes less prominent in REM sleep^{2,70} because of several reasons. First, breathing is predominantly under metabolic control during non-REM sleep and is therefore highly dependent on arterial PCO_2 . Thus, reductions in arterial PCO_2 below the apnea threshold will invariably give rise to central apneas. However, breathing is largely independent of metabolic control during REM sleep, so it is not nearly as dependent on arterial PCO_2 as in non-REM sleep. Second, ventilatory responses to carbon dioxide and hypoxia are brisker in non-REM than in REM sleep, so the potential to hyperventilate is greater in the former than in the latter state. Third, arousal thresholds for arterial PCO_2 and arterial PO_2 are significantly lower in non-REM than in REM sleep. Thus, people are more arousable and therefore more prone to respiratory control system instability in non-REM than in REM sleep. Fourth, the respiratory muscles, save for the diaphragm, are essentially paralyzed in REM but not non-REM sleep. Thus, for any given chemical (e.g., arterial PCO_2) or nonchemical (e.g., arousal) stimulus, the augmentation in ventilation will be greater in non-REM than in REM sleep, making hyperventilation more likely in the former state.

Figure 89-4 Nonhypercapnic central apneas: Cheyne-Stokes and idiopathic CSA. **Upper panel:** Polysomnographic recording of Cheyne-Stokes respiration with a central sleep apnea (CSR-CSA) in a patient with heart failure. Note the absence of rib cage and abdominal motion when there is no tidal volume (VT) excursion, indicating an absence of central respiratory drive. Following apnea, there is a crescendo-decrescendo pattern of VT typical of CSR-CSA in association with a prolonged periodic cycle duration. A and B are the beginning and end of the apnea, respectively. C is the lowest arterial oxygen saturation (SaO₂), so B to C represents the time taken for the lowest arterial SO₂ in the lung at end apnea to be detected by an oximeter placed on the ear (i.e., lung-to-ear circulation time). D is the end of the hyperpnea. Compared with the subject with idiopathic CSA (ICSA) shown in the lower panel, apnea duration in the patient with CSR-CSA (A to B) is similar (21 seconds), but lung-to-ear circulation time (B to C = 26 seconds), total cycle duration (A to D = 65 seconds), and hyperpnea duration (B to D = 46 seconds) are much longer. This is due to lower cardiac output in this patient because total cycle and hyperpnea durations, as well as lung-to-ear circulation time, are inversely proportional to cardiac output. **Lower panel:** Polysomnographic recording of a central apnea in a patient with ICSA. Note that compared with the patient with CSR-CSA in the upper panel, apnea length is similar (A to B = 18 seconds), but lung-to-ear circulation time (B to C = 8 seconds), total cycle duration (A to D = 25 seconds) and hyperpnea duration (B to D = 7 seconds) are much shorter. ECG, electrocardiogram; EEG, electroencephalogram; EMG_{at}, anterior tibialis electromyogram; EMG_{sm}, submental electromyogram; EOG, electrooculogram. (From Hall MJ, Xie A, Rutherford R, et al: Cycle length of periodic breathing in patients with and without heart failure. *Am J Respir Crit Care Med* 154(2 Pt 1):376–381, 1996.)

One factor that might contribute to poor prognosis in CSR-CSA is elevated sympathetic nervous system activity that is known to have a deleterious effect on the prognosis of patients with heart failure.¹⁰² There is evidence that CSR-CSA increases sympathetic nervous activity both during sleep and during wakefulness,¹⁰³ probably via intermittent apnea-related hypoxia and arousals from sleep.¹⁰⁴⁻¹⁰⁶ High sympathetic nervous activity induces activation of the aldosterone-renin pathway and reduces myocardial contractility over time due to abnormalities in calcium handling with precipitation of cardiac arrhythmias.⁸³ It is this combination of autonomic dysfunction and propensity to arrhythmias and sudden death that are the presumed mechanisms by which CSA contributes to increased mortality in heart failure.^{79,107}

On the other hand, there is some evidence that CSR-CSA does not cause adverse hemodynamic effects in patients with heart failure. A recent study demonstrated that in contrast to obstructive apneas, during which stroke volume and cardiac output decrease, during central apneas, stroke volume and cardiac output actually increase slightly.⁸⁸ The cause of this effect was not identified, but this observation raises the possibility that under certain circumstances, CSR-CSA may provide some compensatory effect for low cardiac output and may not be entirely detrimental to cardiovascular function.

Treatment

Because few symptoms have been attributed to CSR-CSA, symptomatic targets for therapy are difficult to identify. However, because CSR-CSA is associated with increased risk of morbidity and mortality, a logical aim in treating CSR-CSA would be to reduce morbidity or mortality. Nevertheless, no treatments have been shown to affect these outcomes in randomized trials. Thus, because there are no clear-cut indications for treating CSR-CSA, a decision to treat CSR-CSA rests on clinical judgment and the following possibilities can be considered with the proviso that therapies that reduce the severity of CSR-CSA may not lead to improvements in patient symptoms, quality of life, or long-term outcomes. All interventions in current use for CSR-CSA require further study to assess their long-term effectiveness and safety.

Treatment of Heart Failure

Because CSR-CSA arises as a consequence of heart failure, it is reasonable to optimize pharmacologic and device treatments for the underlying heart failure. A few nonrandomized observational studies suggest that angiotensin-converting enzyme inhibitors,¹⁰⁸ β -blockers,¹⁰⁹ and cardiac resynchronization therapy¹¹⁰ may reduce the severity of CSR-CSA in CHF. However, these findings have not been confirmed in randomized trials, and one large epidemiologic study showed no reduction in frequency or severity of CSR-CSA with institution of β -blockers.⁷⁹ In one study, atrial overdrive pacing led to a reduction in the AHI in patients with bradyarrhythmias and CSA, but without heart failure.¹¹¹ However, these findings have not been reproduced. In another small study, it was reported that cardiac transplantation for end-stage heart failure reduced severity of CSR-CSA.⁷³ Although consideration can be given to the implementation of one or more of the previ-

ously mentioned approaches, none of them is specifically indicated for therapy of CSR-CSA, and their use should be reserved to treat the underlying heart failure as required.

Positive Airway Pressure

Continuous Positive Airway Pressure. *Continuous positive airway pressure* (CPAP) has been studied extensively in patients with heart failure and CSR-CSA. Its acute application in patients with heart failure increases intrathoracic pressure, thereby reducing right and left ventricular volumes (i.e., preload), left ventricular transmural pressure (i.e., afterload), and the work of breathing by unloading the inspiratory muscles.^{103,112} It also augments stroke volume and cardiac output in those with elevated left ventricular filling pressures but has the opposite effect in those with normal or reduced left ventricular filling pressures.¹¹³

Several small randomized trials in heart failure patients with CSR-CSA lasting 1 to 3 months have demonstrated that CPAP reduces the AHI by 50% to 60%.^{103,114} The means by which it reduces the AHI are not well understood but may include raising lung volume, thereby increasing the lung O₂ reservoir and thus dampening fluctuations in PaO₂, reducing lung water and thus pulmonary irritant receptor stimulation, and reducing ventilation and allowing arterial PCO₂ to rise above the apnea threshold.¹⁰³ Other small randomized trials in heart failure patients with CSR-CSA also demonstrated that CPAP increases left ventricular ejection fraction, reduces mitral regurgitation, and decreases sympathetic nervous system activity.^{103,115}

The largest randomized trial involving CPAP was the *Canadian Positive Airway Pressure for Patients with Central Sleep Apnea and Heart Failure* (CANPAP), which involved 258 patients over a mean and maximum follow-up of 24 and 64 months.¹¹⁶ CPAP reduced the AHI by approximately 55%, improved left ventricular ejection fraction and 6-minute walking distance, and reduced sympathetic nervous system activity. However, it had no effect on the primary outcome, which was heart-transplant free survival. Therefore, it cannot be recommended for routine use as therapy for CSR-CSA. However, in a post hoc analysis of the trial, patients in whom CPAP reduced the AHI to less than 15 had significantly higher heart-transplant free survival than the control group and the CPAP subgroup in whom the AHI remained above 15.¹¹⁷ These results suggest that a trial of CPAP may be given to heart failure patients with CSR-CSA and, if their AHI is reduced to below 15, then CPAP can be continued because of its potential to reduce morbidity and mortality. However, if the AHI remains above 15, CPAP should be stopped because of the potential for harm.¹¹⁷

Adaptive Servoventilation. *Adaptive servoventilation* (ASV) is a form of positive airway pressure specifically designed to alleviate CSR-CSA. For CSR-CSA, ASV is analogous to a cardiac pacemaker: When it detects a central apnea, it provides intermittent pressure support ventilation, but when it detects that the patient is breathing spontaneously, inspiratory assist is turned off. In heart failure patients with CSR-CSA, it causes a greater fall in the AHI than CPAP, bilevel positive airway pressure, and supplemental O₂.¹¹⁸⁻¹²⁰ However, the clinical effects of ASV in heart failure patients with CSR-CSA are inconsistent. In one randomized trial involving 72 patients over 3 months, ASV did not cause any

significant changes in left ventricular ejection fraction, NT-proBNP level, or quality of life compared with control.¹²¹ In another randomized trial involving 26 patients over 4 weeks, ASV improved an objective measure of alertness and reduced BNP levels but had no effect on LVEF, subjective daytime sleepiness, simulated driving performance, or quality of life.⁹³ There have been no long-term randomized trials of ASV that have assessed effects on morbidity or mortality. Accordingly, there are insufficient clinical outcomes data from randomized trials to support the use of ASV to treat CSR-CSA in patients with heart failure. Further evidence from large-scale randomized trials is required.

Supplemental Oxygen. Supplemental oxygen reduces central apnea-related dips in arterial PO_2 , thereby reducing peripheral chemoreceptor stimulation; this reduces loop gain and lessens the chance of ventilatory overshoot and dips in arterial PCO_2 below the apnea threshold.¹²² Where PCO_2 has been measured during supplemental oxygen administration, it was reported to increase when the AHI was markedly reduced,¹²³ but remain the same when the AHI only decreased marginally,¹²⁴ suggesting that one of the mechanisms by which oxygen attenuates CSR-CSA is via dampening of ventilation and raising PCO_2 above the apnea threshold.

Small randomized trials, from one night to 1 month duration, have demonstrated that nocturnal oxygen reduces AHI by approximately 50% in heart failure patients with CSR-CSA.^{123,125-127} However, the effects of oxygen on physiologic and clinical outcomes have been inconsistent. Staniforth and colleagues¹²⁶ found that supplemental oxygen for 1 month reduced overnight urinary norepinephrine excretion but had no effect on daytime plasma norepinephrine, brain natriuretic peptide, neurocognitive function, sleepiness, or quality of life. In another randomized trial, Andreas and colleagues¹²⁵ reported that administration of nocturnal oxygen for 7 days to 22 patients with heart failure improved peak oxygen consumption and ventilatory efficiency but had no effect on quality of life. Arzt and colleagues¹²⁸ allocated 10 consecutive patients to nocturnal oxygen and the next 16 consecutive patients to CPAP at 8 to 10 cm H_2O for 3 months. Both CPAP and oxygen reduced the AHI by 67%, but only CPAP improved ventilatory efficiency and LVEF. Neither intervention had any effect on peak exercise oxygen consumption. The *Home Oxygen Trial* (HOT)¹²⁹ randomized 51 patients to receive or not receive supplemental oxygen over 1 year. Those who received oxygen had a significant reduction in severity of CSR-CSA and a significant improvement in quality of life as measured by the Specific Activity Scale compared with the control group. However, there was no difference in cardiac event rates among the groups.

Although oxygen attenuates CSR-CSA in patients with heart failure and can reduce nocturnal sympathetic activity, there is no consistent evidence that it improves cardiovascular function or clinical outcomes in such patients. Moreover, administration of supplemental oxygen to patients with heart failure could cause hyperoxia, and by doing so, induce oxidative stress that can exert adverse hemodynamic effects, such as raising vascular resistance, blood pressure, and left ventricular filling pressure, and lowering cardiac output.¹³⁰⁻¹³² Therefore, there is currently

insufficient evidence to support the use of oxygen to treat CSR-CSA in patients with heart failure.

Respiratory Stimulants. Acetazolamide is a carbonic anhydrase inhibitor that causes a metabolic acidosis that increases the stimulus to breathe while lowering the arterial PCO_2 apneic threshold.¹³³ One small 6-day randomized trial demonstrated a modest (38%) reduction in the AHI in heart failure patients with CSR-CSA in association with reductions in daytime sleepiness and fatigue.¹³⁴ Theophylline is an adenosine antagonist that stimulates central respiratory drive and augments cardiac contractility. In a 5-day randomized trial involving 15 patients with heart failure and CSR-CSA, theophylline reduced the AHI but did not improve left ventricular ejection fraction.¹³⁵⁻¹³⁷ However, although once used widely for therapy of acute heart failure, theophylline is no longer used for this purpose because it increases the risk of cardiac arrhythmias and sudden death.^{138,139} Consequently, neither of these agents can be recommended for therapy of CSR-CSA.

Carbon Dioxide. Raising arterial PCO_2 above the apnea threshold either by inhalation of carbon dioxide or the addition of dead space abolishes CSR-CSA instantaneously in patients with heart failure (Fig. 89-6).^{66,140} However, there is no evidence that raising PCO_2 through these means provides any clinical benefits. Moreover, because carbon dioxide increases sympathetic nervous activity and disrupts sleep¹⁴¹ and because no long-term studies have demonstrated its safety or clinical efficacy, it cannot be recommended for therapy of CSR-CSA.

Transvenous Phrenic Nerve Pacing. Modulation of respiration by unilateral transvenous phrenic nerve stimulation via the superior vena cava is under investigation as a treatment for CSR-CSA. A small, open-label study over one night, during which intermittent phrenic nerve stimulation was delivered for several minutes, was associated with a reduction in the AHI. However, the study design and pattern of intermittent phrenic stimulation were not well defined, making it difficult to evaluate the results.¹⁴² Further studies are awaited to determine whether such an intervention is feasible for chronic use and whether it improves clinical outcomes.

Central Sleep Apnea Associated with Cerebrovascular Disease. Nonhypercapnic CSA has been observed in 10% to 15% of patients with cerebrovascular accidents.^{143,144,144a} Its pathogenesis and clinical features have not been well described. However, several studies have found no relationship between the presence of CSA and the location, size, or type of stroke.^{143,144} In some patients, CSA appears in a CSR-CSA pattern. In such cases, CSR-CSA was invariably associated with asymptomatic left ventricular systolic dysfunction.¹⁴⁵ This observation strongly suggests that CSR-CSA in patients with stroke is related to underlying occult cardiac dysfunction and therefore probably shares the same pathogenesis as CSR-CSA in patients with heart failure. However, neither the clinical significance of this finding in patients with stroke nor the therapeutic approach have been studied in any depth. Nevertheless, the implications of finding CSR-CSA in patients following stroke

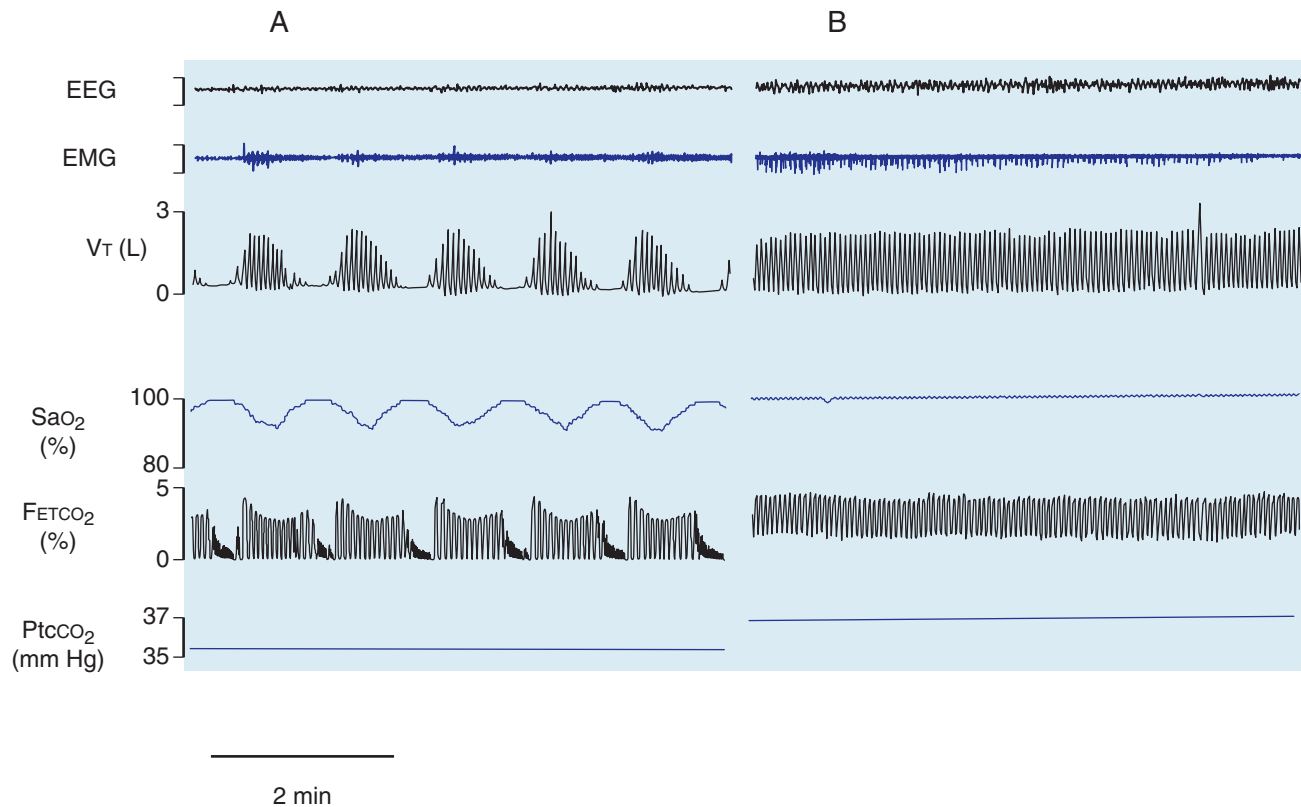

Figure 89-6 Inhaled carbon dioxide abolishes Cheyne-Stokes respiration. Polysomnographic recordings are shown from a patient with recurrent central apneas associated with Cheyne-Stokes respiration during stage 2 sleep while breathing air (**A**) and 1% carbon dioxide in air (**B**). Note abolition of both central apneas on the tidal volume (VT) trace and of recurrent decreases in arterial oxygen saturation (SaO_2) during carbon dioxide inhalation, in association with an increase in transcutaneous PCO_2 (PtCO_2) of 1.6 mm Hg. EEG, electroencephalogram; EMG, submental electromyogram; FETCO_2 , end-tidal carbon dioxide concentration. EEG, electroencephalogram; EMG, electromyogram. (From Lorenzi-Filho G, Rankin F, Bies I, et al: Effects of inhaled carbon dioxide and oxygen on Cheyne-Stokes respiration in patients with heart failure. *Am J Respir Crit Care Med* 159:1490–1498, 1999.)

is that one should investigate for evidence of left ventricular systolic dysfunction.

Central Sleep Apnea Associated with Atrial Fibrillation. Among patients with heart failure, atrial fibrillation is associated with increased odds of having CSR-CSA.⁷⁹ In patients with CSA, but without heart failure or cerebrovascular or renal disease, atrial fibrillation was observed in 27% versus only 1.7% of patients with OSA and 3.3% of those without sleep apnea.¹⁴⁶ The reason for the strong association between CSA and atrial fibrillation was not identified. However, the most likely possibility is that atrial fibrillation predisposes to CSA by mechanisms similar to those of heart failure, by lowering cardiac output and raising pulmonary venous pressure and thereby triggering hyperventilation and hypocapnia through stimulation of pulmonary vagal irritant receptors.

Central Sleep Apnea Associated with Renal Failure. CSA has also been described in patients with end-stage renal disease.^{147,148} Prevalence rates are difficult to estimate because many of the studies are small. In earlier studies the prevalence of CSA was reported to be 9% to 75%.¹⁴⁸⁻¹⁵⁰ In a more recent study of 89 patients with stage 4 or 5 chronic kidney disease and 75 patients with end-stage renal disease on hemodialysis, CSA was uncommon and the median central apnea index was 0 to 0.7.¹⁵¹ However, the combination of obstructive, central, and mixed events is frequently

reported in hemodialyzed patients with end-stage renal disease.^{149,150,152} Predictors for CSA include atrial fibrillation, an increased cardiothoracic ratio on a chest radiograph, and low PCO_2 , all of which suggest mechanisms for CSA in renal disease similar to those in heart failure and atrial fibrillation, including fluid volume overload.¹⁴⁸ Non-randomized studies showed that one night of CPAP alleviated CSA in six patients with end-stage renal disease¹⁵⁰ and that conversion from conventional thrice-weekly hemodialysis to more intense nocturnal hemodialysis in 14 subjects with a mixture of OSA and CSA reduced all types of events in association with an increase in PCO_2 .¹⁴⁹ Nocturnal fluid removal may have contributed to alleviation of CSA and other types of respiratory events, probably through reductions in overnight fluid shifts into the neck, in the case of OSA, and into the lungs, in the case of CSA.^{89,153}

Central Sleep Apnea Associated with Acromegaly. Acromegaly is associated with high prevalences of both OSA and CSA. In one study, 20% of 54 patients with acromegaly had CSA.¹⁵⁴ Slopes of the hypercapnic ventilator responses were related to GH and IGF-1 levels, suggesting that these substances have effects on breathing control. Moreover, the severity of CSA was directly related to carbon dioxide responsiveness and the level of IGF-1.

Clinical features of CSA in acromegaly have not been well characterized but appear to be similar to that of OSA, including loud snoring and excessive daytime sleepiness.¹⁵⁴

In one nonrandomized study involving 19 patients with acromegaly and sleep apnea, treatment of acromegaly by the somatostatin analogue, octreotide, was associated with a 50% decrease in the AHI that involved both central and obstructive events.¹⁵⁵ Similarly, in another nonrandomized study involving 6 patients with acromegaly and a mixture of OSA and CSA, treatment of acromegaly by transsphenoidal adenomectomy alleviated both CSA and OSA, but effects on symptoms of sleep apnea were not assessed.¹⁵⁶

High-Altitude Central Sleep Apnea (see Chapter 77). At high altitude, hypobaric hypoxia provokes hyperventilation, which causes arterial PCO_2 to fall recurrently below the apnea threshold during sleep.¹⁵⁷ At high altitude, natives of both high and low altitudes can exhibit CSA, but not everyone is susceptible.¹⁵⁸ For unknown reasons, men are more likely to develop CSA at high altitude than women, just as they are more prone to other forms of nonhypercapnic CSA.¹⁵⁹

In lowlanders, there is a progressive increase in the frequency of central events and a reduction in the periodic breathing cycle length with increasing altitude from 2400 m to 7546 m.¹⁶⁰⁻¹⁶² The progressive reduction in cycle length is probably due to increasing cardiac output and therefore reduced lung-to-chemoreceptor circulation time. Over time, as individuals acclimatize to high altitude, CSA attenuates.^{163,164} This is due mainly to metabolic compensation for respiratory alkalosis that happens over 2 to 3 days. As a consequence, the difference between arterial PCO_2 and the apnea threshold increases, causing periodic breathing to dampen over time.¹³³ Complaints related to CSA at high altitude include poor-quality sleep, nocturnal dyspnea, morning headaches, and impaired cognition.¹⁶⁵⁻¹⁶⁸

Return to low altitude quickly reverses high-altitude CSA. Specific therapies for CSA while at altitude include supplemental oxygen that causes arterial PCO_2 to rise above the apnea threshold with immediate reversal of CSA and subjective improvement in sleep quality.¹⁶⁷ Respiratory stimulants can alleviate high-altitude CSA. For example, in a randomized trial involving 30 subjects with high-altitude CSA, acetazolamide or theophylline virtually eliminated CSA. However, 60% of subjects on acetazolamide reported paresthesias and altered taste and 70% of subjects receiving theophylline complained of palpitations.¹⁶⁹

In a randomized trial involving 33 subjects at high altitude, the sedative medication temazepam caused a modest reduction in severity of CSA.¹⁷⁰ The proposed mechanism of action of this sedative is that by reducing the frequency of arousals from sleep it prevents abrupt hyperventilation and consequent fall in PCO_2 below the apnea threshold. At present, although firm recommendations cannot be given regarding the pharmacologic treatment of high-altitude CSA, it seems most logical to use supplemental oxygen and/or acetazolamide because they are routinely used at high altitude in any case to correct hypoxemia and to prevent acute mountain sickness and high-altitude pulmonary edema, respectively.

Opioid-Induced Central Sleep Apnea. Both OSA and CSA have been described in patients using opioids.¹⁷¹⁻¹⁷³

There are at least two physiologic effects of opioids that could predispose to CSA. First, opioids activate endogenous opioid receptors in areas of the brain that inhibit inspiratory drive and cause respiratory depression, particularly in the pre-Botzinger complex of the medulla.¹⁷⁴ Exaggeration of such inspiratory depression at the onset of sleep could therefore cause central apneas and hypopneas. If so, then one would expect it to happen in the presence of hypercapnia. However, when arterial blood gas analyses have been performed in wake subjects with methadone-related CSA, PCO_2 has generally been within normal limits and has borne no relationship to the presence or severity of CSA.^{172,175-177} Consequently, opiate-induced CSA appears not to be associated with hypercapnia and respiratory depression per se but rather to fall into the nonhypercapnic category.

Second, opioids also cause arterial and venous dilation in both the pulmonary and systemic circulation via stimulation of histamine receptors.^{178,179} This venous dilating effect causes peripheral venous pooling and, in patients with acute cardiogenic pulmonary edema, this reduces left ventricular filling pressure and pulmonary congestion.¹⁸⁰ It is therefore possible that chronic opioid use could cause chronic venous pooling in the capacitance vessels of the splanchnic circulation and legs. If so, there may be substantial rostral fluid shift on lying down at night that could accumulate in the lungs and stimulate vagal irritant receptors that would provoke hyperventilation and a fall in PCO_2 toward the apnea threshold similar to that described in patients with heart failure and CSA.^{89,181} However, such a mechanism remains speculative.

The severity of CSA in those on narcotics may vary from night to night depending on the dosage: the higher the dose, the higher the AHI.^{172,182,183} In retrospective studies of opioid users referred to sleep clinics, the prevalence of isolated CSA ranged between 14% and 30%.^{172,182,184,185}

Central nervous system symptoms of opioids include dizziness, nausea, neurocognitive impairment, and hypersomnolence.¹⁸⁶ The extent to which these symptoms are due to opioid use per se or CSA is difficult to determine. Chronic opioid use can increase the risk of sudden death, possibly due to cardiac arrhythmias, but there is no evidence to date that this is related to CSA or other sleep-related breathing disorders.¹⁸⁷

In patients with opioid-induced CSA, opioid withdrawal resolves or reduces the severity of CSA and daytime hypersomnolence.^{188,189} However, opioid withdrawal is often not feasible because of addiction or chronic pain. CPAP, BiPAP, and ASV have been tested for therapy of opioid-induced CSA in small, retrospective, nonrandomized trials. Conflicting results have been reported for CPAP from two small retrospective studies: in one, CPAP was ineffective and, in the other, it reduced the AHI to less than or equal to 5 in 54% of individuals.¹⁹⁰ In this latter study, the addition of supplemental oxygen to CPAP abolished CSA in 81%.¹⁹⁰ BiPAP with supplemental oxygen abolished CSA in a further 10% of subjects. ASV has been evaluated in only a few small studies with conflicting results.^{189,191,192,192a}

Complex Sleep Apnea. Complex sleep apnea was originally described as the emergence of CSA in patients with

OSA during or following initiation of CPAP therapy, called *CPAP-emergent CSA*. Subsequently, the emergence of CSA in patients with OSA has also been described following maxilomandibular advancement surgery,^{193,194} application of mandibular advancement devices,¹⁹⁵ tracheostomy,¹⁹⁶ and nasal surgery¹⁹⁷ and is called *treatment-emergent CSA*. There is, however, controversy as to the definition of complex sleep apnea and whether or not it is a distinct entity. The term *complex sleep apnea* has also been used to describe persistence of only the central events following treatment of a combination of central, mixed, and obstructive sleep apnea, called *CPAP-persistent CSA*. Therefore, a clear definition of complex sleep apnea has yet to emerge.^{198,199} For the purposes of this chapter we use the term *complex sleep apnea* to include both *treatment-emergent CSA* and *treatment-persistent CSA*.

The main postulated mechanism of CSA emergence on initiation of CPAP and the other therapies mentioned earlier in patients with OSA is that relief of upper airway obstruction in someone with a high central respiratory drive facilitates augmented ventilation that reduces PCO_2 below the apneic threshold.^{198,200}

During CPAP titration in patients with OSA with and without heart failure, the prevalence of treatment-emergent CSA ranges from 5% to 20%.²⁰⁰⁻²⁰⁵ After 2 to 3 months' acclimatization to CPAP, treatment-emergent CSA dissipates in greater than 50% of subjects without heart failure.^{201,203} Treatment-emergent CSA has also decreased over a period of 6 months after tracheostomy.²⁰⁶

In unselected sleep cohorts, risk factors identified for the development of treatment-emergent CSA were poorer sleep efficiency, hypertension, coronary artery disease, heart failure, opioid use, and more severe OSA.^{201,203,207} In the heart failure population, predictors for development of CPAP-emergent CSA included older age, lower arterial PCO_2 , poorer New York Heart Association class, less diuretic therapy, and increased ventilatory responsiveness to CO_2 .²⁰⁵ However, up to one third of those with CPAP-emergent CSA do not have any of these risk factors.²⁰⁸

In most patients no specific treatment is necessary for treatment-emergent CSA because, over 2 to 3 months, these events dissipate in the majority of subjects. Furthermore, even in those with persistent treatment-emergent CSA, daytime sleepiness is usually alleviated.²⁰¹ For those in whom complex CSA persists despite CPAP or other therapies, there is no available information on long-term consequences.

Treatments for persistent treatment-emergent CSA include BiPAP, ASV, oxygen, and addition of dead space. In most studies, decisions to treat complex CSA were not based on patient symptoms. Studies with BiPAP are conflicting, with one study demonstrating an improvement²⁰⁹ and two studies showing no improvement in CSA.^{210,211} A retrospective study evaluating the addition of 50 to 200 mL of dead space via a nonvented mask to a standard CPAP unit reported abolition of CSA.²¹² In retrospective studies ASV was reported to abolish CPAP-emergent CSA in 79% to 100% of patients on titration studies.²¹³⁻²¹⁵ In small prospective randomized trials, treatment of CPAP-emergent CSA was abolished by ASV in 97% to 100% of patients after between 6 and 12 weeks.^{205,207,216}

Primary Nonhypercapnic Central Sleep Apnea

Idiopathic Central Sleep Apnea. *Idiopathic CSA* (ICSA) is a form of CSA in which there are central apneas and hypopneas without evidence of cardiovascular diseases or other lesions that might explain their presence. Two large epidemiologic studies reported a prevalence of CSA of 0.4% in men²¹⁷ but essentially 0% in women.²¹⁸ Because these populations were considered healthy, one can assume that most cases of CSA they identified were ICSA. Accordingly, ICSA appears to be rare.

Similar to CSR-CSA, patients with ICSA hyperventilate with low arterial PCO_2 during both wakefulness and sleep. The tendency to hyperventilate is related to increased responsiveness of the peripheral and central chemoreceptors that increase loop gain and lead to respiratory instability.^{71,219,220} Episodes of central apneas and hypopneas during sleep are typically precipitated by an abrupt increase in ventilation usually triggered by an arousal following which arterial PCO_2 drops below the apnea threshold. Their dependence on hypocapnia is illustrated by the observation that raising arterial PCO_2 either by inhalation of a small concentration of carbon dioxide or addition of deadspace immediately abolishes this breathing disorder.²²¹ As in CSR-CSA, central events are seen predominantly during non-REM sleep with a reduction in frequency or complete cessation of events during REM sleep for similar reasons. Compared with heart failure patients with CSR-CSA, the durations of the hyperpnea and periodic breathing cycle are much shorter due to shorter lung-to-chemoreceptor circulation time and higher stroke volume and cardiac output (see Fig. 89-4).⁷⁶

In some respects, the clinical presentation of ICSA resembles that of OSA. Patients are usually middle-aged or older men who are overweight, complain of snoring, have restless sleep, and may also complain of excessive daytime sleepiness, but they more often complain of insomnia. There are no studies on the natural history of this disorder, so its overall clinical significance is difficult to assess. Treatments assessed include the respiratory stimulant acetazolamide,^{169,222} which provides a constant stimulus to breathe and therefore reduces fluctuations in ventilation. Studies evaluating acetazolamide have been nonrandomized and produced inconsistent results without careful evaluation of clinical outcomes. Therefore acetazolamide cannot be recommended as chronic treatment for this disorder at this time.

Because increased arousals and sleep instability can precipitate CSA, sedative medications have been tested in order to reduce arousability and thereby alleviate ICSA. In a non-randomized, open-label, 9-week trial of the nonbenzodiazepine GABA receptor agonist, zolpidem,²²³ the AHI fell by 55% in association with a reduction in arousal frequency and subjective daytime sleepiness. In a one-night randomized trial, the benzodiazepine hypnotic, triazolam,²²⁴ was also reported to reduce the AHI modestly in association with a reduction in arousal frequency. Because both of these studies included only small numbers of subjects, much larger randomized studies will be required before more evidence-based treatment recommendations can be made. There are no published studies evaluating the effects of positive airway pressure devices in ICSA.

Key Points

- Central sleep apnea (CSA) is a rare but heterogeneous disorder in which the arterial PCO_2 comes to lie below the apnea threshold during sleep, either because the PCO_2 falls or the apnea threshold rises.
- In CSA, there are recurrent reductions (hypopnea) or cessations (apnea) of airflow due to a reduction in central respiratory drive in the absence of airflow limitation from upper airway obstruction.
- Classification of CSA is based on the presence or absence of hypercapnia. There are two major types:
 - CSA associated with hypercapnia arises from impaired central respiratory drive or neuromuscular weakness affecting the respiratory muscles that is exacerbated during the transition from wakefulness to sleep by the withdrawal of the waking drive to breathe and is most prominent in *rapid eye movement* (REM) sleep.
 - CSA associated with normocapnia or hypocapnia (i.e., nonhypercapnic) is often associated with augmented central respiratory drive that predisposes to alternating periods of hyperventilation that drive PCO_2 recurrently below the apnea threshold. It is most prominent in non-REM sleep.
- Cheyne-Stokes respiration with CSA, a form of nonhypercapnic CSA usually associated with heart failure, is characterized by a waxing and waning pattern of respiration typically seen during non-REM sleep and is associated with increased mortality risk.
- Complex sleep apnea is a form of CSA that arises following treatment of obstructive sleep apnea by continuous positive airway pressure or other interventions (i.e., treatment-emergent CSA) or persists following treatment of a combination of central, mixed, and obstructive sleep apnea (i.e., treatment-persistent CSA).

INTRODUCTION

Since the recognition of the first cases of *acquired immunodeficiency syndrome* (AIDS) in 1981, our understanding of *human immunodeficiency virus* (HIV) and its myriad infectious and noninfectious complications has markedly increased. The prognosis for persons infected with HIV has undergone dramatic change for those with access to effective combination *antiretroviral therapy* (ART) to suppress HIV replication and medications for treatment and prevention of HIV-associated complications. ART in this chapter refers to the use of *combination ART*, often taken in a fixed-dose combination, that suppresses viral replication and prevents selection of drug-resistant HIV. These therapeutic advances have resulted in a dramatic decline in the incidence of new AIDS cases and in the number of AIDS-associated deaths in countries where this care is widely and consistently available.¹ Unfortunately, access to ART and other medications is not universal, and an HIV vaccine remains elusive. Therefore, efforts to prevent the spread of new HIV infection, to identify and treat those persons who are already HIV infected, and to slow the progression from HIV to AIDS continue to be worldwide priorities.

The lungs are one of the chief target organs of HIV and, accordingly, a major source of morbidity and mortality. The spectrum of pulmonary manifestations is broad and includes many infectious and noninfectious complications ([Table 90-1](#)).² These complications include diseases that are AIDS-defining (e.g., *Pneumocystis pneumonia*) or HIV-associated (e.g., bacterial pneumonia), disorders that are not classified as HIV-associated but appear to be more common in those with HIV infection (e.g., lung cancer, *pulmonary arterial hypertension* [PAH], and *chronic obstructive pulmonary disease* [COPD]), and conditions whose association with HIV is inconclusive or purely coincidental (e.g., sarcoidosis). HIV-infected patients may also frequently experience critical illness either as a result of pulmonary complications or other diseases and, although uncommon, lung transplantation in HIV-infected patients has been performed.^{3,3a} This chapter provides a brief review of the epidemiology of HIV infection and its immunologic abnormalities, followed by an approach to the evaluation of pulmonary disease in an HIV-infected patient. Then, the major HIV-associated pulmonary diseases are discussed, with an emphasis on clinical features, diagnosis, treatment, and prevention.

EPIDEMIOLOGY

The AIDS epidemic has had a major impact throughout the world. A disproportionate number of all of the HIV-infected people in the world live in low- and middle-income countries, especially in sub-Saharan Africa, which has the world's highest prevalence of HIV infection. Global estimates indicate that 35.3 million people were living with

HIV in 2012.⁴ Overall, approximately 0.8% of adults aged 18 to 49 years are infected with HIV worldwide. In sub-Saharan Africa, 4.9% of adults are living with HIV. Following sub-Saharan Africa, the regions with the highest burden of HIV infection are the Caribbean, Eastern Europe, and Central Asia. The *Centers for Disease Control and Prevention* (CDC) estimates that 1.1 million people were living with HIV in the United States as of 2012.⁵

Encouragingly, new HIV infections have declined over the past decade. Although 2.3 million people worldwide were newly infected with HIV in 2011, this number represents a 20% drop from the number in 2001.⁴ AIDS-related mortality has also declined: in 2012, 1.6 million people died of AIDS-related causes compared with 2.3 million in 2005.⁴ Because survival has improved for HIV-infected patients since the introduction of ART, more people are living with HIV in the United States than ever before.⁶ Furthermore, HIV-infected adults in clinical care in the United States are more likely in the recent era to be prescribed ART, to have a suppressed HIV viral load, and to have a higher median CD4⁺ T cell-count.⁷

The gender and racial/ethnic demographics of HIV-infected populations vary worldwide. In sub-Saharan Africa, women account for approximately 58% of people estimated to be living with HIV.⁴ In the United States, women comprise approximately 21% of adult AIDS cases.⁸ Although early in the epidemic HIV was predominantly seen among non-Hispanic white men who have sex with other men (MSM), HIV is increasingly affecting minorities, with new infections disproportionately represented in minorities, especially blacks and Hispanic/Latin Americans.^{9,10}

IMMUNOLOGIC ABNORMALITIES

After infection with HIV and without ART, HIV-infected persons experience a gradual but inexorable loss of host immunity that has been characterized as a syndrome of immune dysregulation, dysfunction, and deficiency, involving many components of the immune system. HIV is tropic for CD4⁺ lymphocytes and monocytes.¹¹ After initial infection, HIV leads to massive depletion of CD4⁺ lymphocytes of the effector-memory type from mucosal associated lymphoid tissue.¹² During the chronic phase of untreated HIV infection, there is a generalized immune activation and ultimately a progressive decline in the naive and memory T-cell pool that results in systemic CD4⁺ lymphocyte depletion.^{12,13} As well as being decreased in number, T cells are also dysfunctional and mount abnormal host responses to T-cell-dependent antigens. HIV infection is also associated with B-cell dysfunction. Abnormal polyclonal activation, hypergammaglobulinemia, and lack of specific antibody responses ensue. This combination of immune dysfunction, dysregulation, and depletion of CD4⁺ lymphocytes results in a substantially increased risk for infections and other complications. Effective ART substantially decreases opportunistic infections and mortality in HIV-infected patients.¹ The chronic immune activation that takes place in the second phase of HIV infection can be decreased by ART.¹² Nonetheless, immune activation and chronic inflammation can persist, particularly in those who initiated ART at lower CD4⁺ cell counts or who have treatment interrupted.^{14,15}

Premature mortality and comorbidities such as cardiovascular, renal, and liver disease have been associated with residual inflammation and immunodeficiency despite treatment with ART.^{16,17}

HIV infection also causes alteration in several lines of host defense in the lung and respiratory tract that contribute to an increased risk for pulmonary infections.¹⁸ These include abnormalities in both mucociliary function and soluble defense molecules within respiratory secretions. Within the lung parenchyma, innate and adaptive immune responses to pathogens may be impaired. For example, alveolar macrophages from HIV-infected individuals have been shown to have deficiencies in pathogen recognition, including abnormalities in Toll-like receptor 4 signaling.^{19,20} Bronchoalveolar CD4⁺ T cells from HIV-infected individuals display impaired responses to important respiratory pathogens, including influenza and *Mycobacterium tuberculosis*.²¹ Evidence also suggests that HIV results in chronic stimulation and activation of inflammatory cells within the alveolar space.²² Furthermore, animal models suggest that HIV-related proteins may disrupt the barrier function of the alveolar epithelium.²³

The consequences of persistently increased inflammation and immune activation related to HIV on the pathogenesis of chronic lung complications are less clear. Within the alveolar space, HIV infection is associated with changes in the cellular profile¹⁸; however, the mucosal depletion of CD4⁺ T cells that takes place in the gastrointestinal tract does not appear to happen within the lung. Instead, *bronchoalveolar lavage* (BAL) fluid from HIV-infected individuals has more CD4⁺ T cells than does the terminal ileum.²⁴ Lung cells that can be infected with HIV include alveolar macrophages, T cells, and fibroblasts.¹⁸ While alveolar macrophages have been viewed as a potential reservoir of HIV-infected cells within the lung, recent evidence suggests that T cells instead may be a long-lived reservoir of infection within the lung.²⁵ The clinical significance of the lung as a protected compartment for HIV-infected cells is incompletely understood.²⁶

DIAGNOSTIC APPROACH

The evaluation of an HIV-infected patient with pulmonary disease is aimed at making a specific diagnosis. Definitive diagnosis is preferred over empirical therapy for a number of reasons. Although each of the HIV-associated pulmonary diseases has characteristic clinical and radiographic features, these features overlap. Occasionally, the presenting features are atypical or more than one pulmonary disease is present. Without appropriate therapy, HIV-infected patients with pneumonia can progress rapidly to respiratory failure and death. The therapies used to treat HIV-associated pulmonary diseases have substantial toxicities and interactions with other medications.

The evaluation should begin with the history and physical examination.²⁷ Laboratory testing should be performed and a chest radiograph obtained in patients with suspected pulmonary disease. Frequently, the results of this evaluation suggest a specific differential diagnosis and management plan. Occasionally, additional studies such as pulmonary function testing, chest *computed tomography*

(CT), or high-resolution CT are needed to narrow the differential diagnosis and to refine the management plan.

Owing to their particular importance in the diagnostic evaluation of many patients with known or suspected HIV-related pulmonary disease, the value of CD4⁺ lymphocyte counts and fiberoptic bronchoscopy is briefly reviewed here. The utility of other diagnostic tests is considered in the discussions of the specific complications and disorders that follow this section. Additional information on specific diagnostic tests is also available in Chapter 17.

CD4⁺ LYMPHOCYTE COUNT

The CD4⁺ lymphocyte count is an indicator of an HIV-infected patient's risk for development of a specific opportunistic infection or HIV-associated neoplasm. Many HIV-associated pulmonary diseases present at or below a characteristic CD4⁺ lymphocyte count and are seldom seen at higher counts.²⁸ Exceptions are diseases that can present in persons without HIV infection, such as bacterial pneumonia, tuberculosis, and *non-Hodgkin lymphoma* (NHL). In HIV-infected persons, these diseases can present at any CD4⁺ lymphocyte count, although their incidence increases and their characteristic presentation changes as the CD4⁺ lymphocyte count declines (see later disease discussion).

At CD4⁺ lymphocyte counts less than 200 cells/ μ L, bacterial pneumonia is often accompanied by bacteremia, and *M. tuberculosis* disease is often extrapulmonary or disseminated. Moreover, below this CD4⁺ lymphocyte count, *Pneumocystis* and *Cryptococcus* pneumonia become important considerations, whereas neither typically presents in a patient with a count significantly higher than 200 cells/ μ L. At CD4⁺ lymphocyte counts less than 50 to 100 cells/ μ L, endemic fungi, certain viruses (*cytomegalovirus* [CMV]), protozoa (*Toxoplasma gondii*), nontuberculous mycobacteria (*Mycobacterium avium complex* [MAC]), and *Kaposi sarcoma* (KS) become important considerations. Many of these diseases present with extrapulmonary or disseminated manifestations that may dominate the clinical presentation.

The risk of opportunistic infections is best reflected by the current CD4⁺ lymphocyte count.²⁹ Primary and secondary *Pneumocystis* prophylaxis can be safely discontinued in patients whose CD4⁺ lymphocyte counts increase above 200 cells/ μ L for at least 3 months in response to ART; similar evidence has emerged indicating that it is safe to discontinue prophylaxis against MAC, *Cryptococcus*, *Histoplasma capsulatum*, *Coccidioides immitis*, and *Toxoplasma* when CD4⁺ lymphocyte counts have been restored to greater than certain CD4⁺ thresholds.²⁹

FIBEROPTIC BRONCHOSCOPY

In general, bronchoscopy should be considered for any HIV-infected patient with pulmonary disease whose severity warrants a prompt and accurate diagnosis, for patients with suspected pulmonary KS, for patients with suspected NHL (if other diagnostic procedures are thought to be more hazardous or less likely to provide the diagnosis), for patients whose diagnosis remains unknown despite less invasive diagnostic studies (e.g., induced sputum), and for patients whose empirical therapy is failing. Conventional

contraindications pertain to HIV-infected patients; HIV infection should not be considered a contraindication to bronchoscopy.

The decision to perform BAL with or without *transbronchial biopsy* (TBB) depends on the suspected diagnosis and on the sensitivities of these procedures for that diagnosis. At the beginning of the AIDS epidemic, both BAL and TBB were usually performed during the initial bronchoscopy. Studies demonstrated that the yield from these two procedures was complementary in identifying pathogens: the sensitivity of BAL was 86% and that of TBB 87%; when the two procedures were combined, the sensitivity was 98% for all pathogens and 100% for *Pneumocystis*.³⁰ Currently, BAL alone is generally performed when *Pneumocystis pneumonia* (PCP) is the suspected pathogen.³¹ The sensitivity of BAL fluid examination for *Pneumocystis* is 97% or higher; therefore, a negative BAL fluid examination for *Pneumocystis* rules out the diagnosis of PCP in all but the rarest cases.³¹

In contrast, TBB improves the sensitivity of bronchoscopy for diagnosing a number of other important pathogens, including tuberculosis and endemic fungal pneumonias. Furthermore, tissue confirmation from TBB or another biopsy specimen is required for a definitive diagnosis of invasive aspergillosis, CMV pneumonia, and NHL. Therefore, when the clinical and radiographic features suggest one of these diseases, both BAL and TBB are warranted during the initial bronchoscopy.

INFECTIOUS COMPLICATIONS

In this section, the major pulmonary infectious complications of HIV disease are reviewed according to category of infectious microorganism (see [Table 90-1](#)).

BACTERIA

Early in the AIDS epidemic, bacterial pneumonia accounted for only a small proportion of reported pulmonary diseases. Subsequently, bacterial pneumonia became recognized as a frequent complication of HIV infection and one that often preceded other opportunistic infections. As a result, recurrent bacterial pneumonia (defined as two or more episodes within 12 months) was included as an AIDS-defining illness in the 1993 CDC Expanded Surveillance Case Definition for AIDS.³²

Prior to the ART era, Hirschtick and coworkers³³ in the *Pulmonary Complications of HIV Infection Study* (PCHIS) confirmed the increased incidence of community-acquired bacterial pneumonia in HIV-infected persons. In this study, there were 5.5 episodes of bacterial pneumonia per 100 person-years in the HIV-infected cohort compared with 0.9 episodes per 100 person-years in the HIV-seronegative control cohort ($P < 0.001$). Bacterial pneumonia was more common in HIV-infected patients than in the HIV-seronegative controls, even in the subset of HIV-infected patients with CD4⁺ lymphocyte counts greater than 500 cells/ μ L ($P < 0.004$). Furthermore, the rate of bacterial pneumonia in the HIV-infected cohort increased as the CD4⁺ lymphocyte count declined. The rate of bacterial pneumonia was 2.3 episodes per 100 person-years in subjects with a CD4⁺ lymphocyte count greater than 500

cells/ μ L compared with 10.8 episodes per 100 person-years in persons with a CD4⁺ lymphocyte count less than 200 cells/ μ L. The incidence of bacterial pneumonia was significantly greater in intravenous drug users than in either MSM or female partners of HIV-infected men. Cigarette smoking was also associated with an increased incidence of bacterial pneumonia, especially in HIV-infected individuals with a CD4⁺ lymphocyte count less than 200 cells/ μ L.

During the ART era (1996 to present), the incidence of community-acquired bacterial pneumonia among HIV-infected persons has declined, although not to the same extent as opportunistic pneumonias such as PCP.³⁴ In the CDC-sponsored Adult/Adolescent Spectrum of HIV Disease project, a prospective medical record review of HIV-infected persons aged 13 years and older in 11 U.S. cities, the incidence of recurrent pneumonia declined from 22 per 1000 person-years in 1992 to 10.7 per 1000 person-years in 1997.³⁵ Other studies have reported similar decreases from the use of ART in both community-acquired pneumonia³⁶ and hospital-acquired pneumonia.³⁷ Thus, ART is clearly associated with a decreased risk for bacterial pneumonia. Another reason credited for decreased bacterial pneumonia among HIV-infected patients is the use of *trimethoprim-sulfamethoxazole* (TMP-SMX) as prophylaxis for PCP.³⁸

Yet despite the significant decrease in incidence, bacterial pneumonia remains more frequent in HIV-infected individuals than in noninfected individuals.^{39,40} Furthermore, bacterial pneumonia is a common cause of morbidity and is associated with increased short- and long-term mortality in HIV-infected patients in the ART era.^{38,41} One reason for the persistence of bacterial pneumonia despite effective ART is the high prevalence of cigarette smoking in HIV-infected populations.⁴² Cigarette smoking is associated with substantially increased rates of pneumonia in multiple studies of HIV-infected patients, at all CD4⁺ lymphocyte cell counts,^{33,38,43,44} whereas smoking cessation decreases the risk for pneumonia.⁴⁵ Intravenous drug use remains a significant risk factor for bacterial pneumonia in the ART era. Additionally, neutrophil number and function can be impaired in HIV infection, which may be exacerbated by concomitant cigarette smoking and contribute to increased risk for bacterial pneumonia.

Several bacterial species can cause pneumonia in HIV-infected patients. Similar to community-acquired bacterial pneumonia in non-HIV-infected populations, *Streptococcus pneumoniae* and *Haemophilus* species are the most frequently identified pathogens in people with HIV infection. In several studies, the two organisms have accounted for approximately 50% to 60% of cases combined,^{33,46} and they remain the most commonly isolated bacterial organisms in the ART era.^{47,47a} *Staphylococcus aureus* can be isolated as a cause of community-acquired pneumonia in patients both with and without a history of intravenous drug use.⁴⁷⁻⁴⁹ In addition to being a cause of nosocomial disease, *Pseudomonas aeruginosa* is well recognized as a cause of community-acquired bacterial pneumonia in HIV-infected persons, especially those with advanced AIDS. *S. pneumoniae* and *P. aeruginosa* ([eFig. 90-1](#)) were the two most common bacteria seen in a series of 111 cases.⁴⁸ Although this series included community-acquired as well as hospital-acquired pneumonias, most cases of pneumococcal pneumonia (91%) as well as pseudomonal pneumonia (63%) were community acquired. Other bacteria that are occasionally identified as

causes of community-acquired bacterial pneumonia in HIV-infected persons include atypical organisms such as *Legionella* species, *Rhodococcus equi*, and *Nocardia* species; these are discussed in more detail later.

Of hospital-acquired pneumonias, the two most common bacterial causes in HIV-infected persons are *S. aureus* and *P. aeruginosa*. Both of these organisms are more likely to be isolated in patients with lower CD4⁺ lymphocyte counts.^{37,46} Staphylococcal pneumonia is frequently complicated by bacteremia, methicillin resistance, and high mortality.³⁷ *S. pneumoniae* and *Klebsiella pneumoniae* are also relatively frequent causes of pneumonia in HIV-infected hospitalized patients.³⁷

Clinical Features. In HIV-infected persons, the clinical and radiographic features of bacterial pneumonia are similar to those in immunocompetent persons, with a few important exceptions.⁵⁰ Of note, HIV-infected individuals have a substantially increased risk for bacteremia and invasive disease due to *S. pneumoniae*. The rate of pneumococcal bacteremia in HIV-infected patients has been estimated to be almost 100 times greater than that in age-matched non-HIV-infected persons.⁵¹ Findings that confer greater risk for bacteremic pneumococcal pneumonia include alcohol abuse, cigarette smoking, recent hospitalization, and presence of comorbid illnesses.⁵² The risk of invasive pneumococcal disease is decreased in those on ART and in those who have received pneumococcal vaccine.⁵³ However, while the incidence of invasive pneumococcal disease has decreased in the current era, the clinical presentation can be severe and may be complicated by respiratory failure.⁵⁴ Providers should consider HIV testing for individuals with unknown serostatus presenting with such disease without other obvious risk factors for invasive pneumococcal disease.⁵³

CD4⁺ Lymphocyte Count. Bacterial pneumonia can develop throughout the course of HIV infection and at any CD4⁺ lymphocyte count. As the CD4⁺ lymphocyte count declines, both the incidence of bacterial pneumonia and the frequency of bacteremia increase. Most cases of *P. aeruginosa* pneumonia are seen in HIV-infected patients with a CD4⁺ lymphocyte count less than 100 cells/ μ L, and usually less than 50 cells/ μ L.^{55,56}

Imaging. As illustrated in Figure 90-1, the majority of bacterial pneumonias due to *S. pneumoniae* in HIV-infected patients present with segmental, lobar, or multilobar consolidation on chest radiograph.⁵⁷ Radiographic findings of pneumococcal pneumonia do not appear to be different among patients on ART than in those not on ART.⁵⁸ Although less common, focal or diffuse alveolar patterns as well as interstitial opacities in association with *S. pneumoniae* or *Haemophilus influenzae* are also seen.^{59,60} Pneumonia due to *P. aeruginosa* may present with focal consolidation, similar to pneumococcal or *Haemophilus* pneumonias, although a significant proportion of radiographs demonstrate cavitary opacities.^{55,61}

Diagnosis. The diagnostic approach to bacterial pneumonia is the same for HIV-infected as for non-HIV-infected persons.^{29,62} HIV-infected patients continue to be at increased risk for invasive pneumococcal disease in the

Figure 90-1 Pneumococcal pneumonia. Frontal chest radiograph in a 50-year-old HIV-infected man with positive urinary pneumococcal antigen shows homogeneous opacity with air bronchograms, extending to the pleural surface, representing a “lobar pneumonia” pattern, typical of pneumococcal pneumonia. (Courtesy Stephen Aston, MBChB; Malawi-Liverpool-Wellcome Trust Clinical Research Programme.)

ART era.⁶³ Blood cultures should be obtained, particularly in those with low CD4⁺ cell counts, given the increased risk for bacteremia in this group. Thoracentesis should be considered for patients with pleural effusion, especially if the effusion is large or if there is concern about a possible empyema. Efforts to culture the causative bacteria to enable drug susceptibility testing are especially important in communities where drug-resistant bacteria are prevalent.

Pneumococcal urinary antigen testing offers the potential for early, specific diagnosis. In a study of 70 adults with pneumococcal pneumonia, 47 of whom were HIV-infected, pneumococcal urinary antigen testing had a sensitivity of 81%, specificity of 98%, positive predictive value of 98%, and negative predictive value of 82%.⁶⁴ The test appeared to perform equally well in HIV-infected and non-HIV-infected persons.

Serum procalcitonin and C-reactive protein levels may assist in the early differentiation of bacterial community-acquired pneumonia and pulmonary tuberculosis in HIV-infected patients; procalcitonin and C-reactive protein levels were higher in patients with bacterial pneumonia than in patients with pulmonary tuberculosis, although overlap exists between these causes of pneumonia, particularly in regions endemic for tuberculosis.^{65,65a} Because procalcitonin increases in response to bacterial infections and decreases in the presence of viral infections, levels are sometimes used as a biologic marker of community-acquired bacterial pneumonia.⁶⁶ Elevated procalcitonin levels can predict increased mortality in HIV-infected patients with lower respiratory tract infections, due either to tuberculosis or to bacterial causes.^{66a} However, further studies of these biomarkers in larger cohorts of HIV-infected individuals with pneumonia are needed.

Treatment. The treatment of patients with community-acquired pneumonia is similar for HIV-infected and non-HIV-infected persons (Chapter 33).^{29,62} The choice of antimicrobial agent should be based on a number of factors, such as the results of a sputum Gram stain, the presence of comorbid conditions (e.g., COPD, congestive heart failure, alcohol use), the clinical and radiographic presentation, and the severity of the pneumonia. As in non-HIV-infected persons, treatment should be initiated promptly. Initial empirical therapy should include coverage against frequently identified organisms (e.g., *S. pneumoniae* and *Haemophilus* species). Local prevailing drug resistance patterns must be considered when the antibiotic is selected. Empirical monotherapy with a macrolide is not advised in HIV-infected patients, particularly when they are already on macrolide prophylaxis for MAC, because of increasing pneumococcal resistance to macrolides.²⁹ Patients on TMP-SMX prophylaxis may be more likely to have penicillin- and TMP-SMX-resistant *S. pneumoniae*.⁶⁷ For patients with CD4⁺ lymphocyte counts less than 100 cells/ μ L, especially if associated with recent hospitalization, neutropenia, or broad-spectrum antimicrobial use, consideration should be given to including coverage against *P. aeruginosa*.

Prevention. Pneumococcal vaccine should be given to HIV-infected patients. For adult (age 19 and older) immunocompromised patients including those with HIV who have not been previously immunized, current recommendations from the Advisory Committee on Immunization Practices to the CDC are for the 13-valent pneumococcal conjugate vaccine to be given first followed by 23-valent pneumococcal polysaccharide vaccine at least 8 weeks or more later.⁶⁸ For those who have already received the 23-valent pneumococcal polysaccharide vaccine, the 13-valent pneumococcal conjugate vaccine should be given at least 1 year later. A repeat dose of 23-valent pneumococcal polysaccharide vaccine should be given 5 years after the first, with another dose given after age 65 years. These recommendations may be revised based on ongoing clinical trials; refer to the Advisory Committee on Immunization Practices and CDC, *National Institutes of Health* (NIH), and the *HIV Medicine Association of the Infectious Diseases Society of America* (HIVMA/IDSA) guidelines for additional details.^{29,68} Because influenza is a major risk factor for bacterial pneumonia, prevention also includes yearly administration of inactivated influenza vaccine in all HIV-infected individuals.

Other Bacteria

Legionella pneumonia is an infrequent cause of bacterial pneumonia in HIV-infected patients and can be community acquired or nosocomial.⁶⁹ Cases have been reported in persons with severe immunosuppression and in individuals with well-controlled HIV on ART.⁷⁰ The chest radiograph typically reveals alveolar opacities; bilateral involvement is common. Extrapulmonary manifestations can also be seen, especially of the gastrointestinal tract and central nervous system. In one series, respiratory failure developed in 12 of 15 hospitalized, HIV-infected subjects (80%) with confirmed *Legionella* pneumonia and 3 died.⁷⁰ Although *Legionella pneumophila* is the most common species identified, other *Legionella* species have been reported. Rapid diagnosis

of *Legionella* pneumonia can be obtained with urinary antigen testing. However, cultures and/or serology should still be considered as part of the diagnostic evaluation, in that the urinary antigen primarily detects *L. pneumophila* serogroup 1 and can have a lower sensitivity in cases of mild disease.⁷¹ Its performance has not been prospectively evaluated in HIV-infected patients.

R. equi pulmonary disease has been reported in HIV-infected persons. A review of more than 100 reported cases of *R. equi* infection found that approximately two thirds were in HIV-infected persons, with pulmonary disease present in the majority.⁷² HIV-infected persons were more likely to have *R. equi* bacteremia or extrapulmonary manifestations, or both, than persons without HIV infection. Most cases present when the CD4⁺ lymphocyte count is less than 200 cells/ μ L and usually less than 100 cells/ μ L.⁷² In one multicenter series of 67 HIV-infected patients with *R. equi* infection, the mean CD4⁺ lymphocyte count was 35 cells/ μ L (range, 1 to 183 cells/ μ L).⁷³ The chest radiograph often reveals cavitory lesions that may mimic tuberculosis or nocardiosis, or focal consolidation that may mimic bacterial pneumonia.⁷⁴ Sputum, blood, bronchoscopy, and pleural fluid specimens can establish the diagnosis of *R. equi* pneumonia.⁷³ The optimum treatment regimen and duration are not well defined.⁷² Combination antimicrobial therapy is generally recommended, and treatment for a minimum of 2 months (and frequently 6 months) is often required. Because relapses are common, chronic suppressive therapy is probably indicated.

Nocardia asteroides is the most common species identified in several reports of *Nocardia* infection in HIV-infected patients, and the lung is the most commonly affected site. Most cases present when the CD4⁺ lymphocyte count is less than 200 cells/ μ L. In one series of 30 HIV-infected patients with nocardiosis, the mean CD4⁺ lymphocyte count was 109 cells/ μ L (median 92 cells/ μ L; range, 12 to 266 cells/ μ L).⁷⁵ The presenting symptoms often mimicked tuberculosis. Imaging (eFig. 90-2) usually reveals cavitory lesions or lobar or multilobar opacities, especially in the upper lung zones, although reticulonodular opacities, solitary masses, and pleural effusions are seen also.⁷⁶ Sputum or bronchoscopy can establish the diagnosis of pulmonary nocardiosis. A modified *acid-fast bacilli* (AFB) stain may provide an early presumptive diagnosis in the proper clinical setting. Long-term TMP-SMX is the treatment of choice.

MYCOBACTERIA

Early in the AIDS epidemic, mycobacteria were recognized as major sources of HIV-associated morbidity and mortality. Initially, disseminated MAC was noted to develop in HIV-infected patients. Subsequently, the strong association between HIV and *M. tuberculosis* and nontuberculous mycobacteria, such as *Mycobacterium kansasii*, became clearer. Other nontuberculous mycobacteria are also occasionally identified as causes of pneumonia in HIV-infected persons.

Mycobacterium tuberculosis

Tuberculosis is the most prevalent opportunistic infection complicating the HIV epidemic worldwide. Although other pathogens may predominate in individual areas, no other pathogen poses as great a global threat to persons

immunocompromised by HIV infection as *M. tuberculosis*. Moreover, unlike most HIV-associated infections, *M. tuberculosis* is transmissible from person to person, including to those without HIV infection. In fact, clusters of transmission of tuberculosis that include at least one HIV-infected person are larger, last longer, and have a shorter time period between successive cases than clusters of solely HIV-negative persons.⁷⁷

The AIDS epidemic contributed to a veritable explosion of tuberculosis throughout the world, especially in low-income countries, where it is often the first manifestation of HIV and a leading cause of mortality. The World Health Organization estimated that there were 1.1 million cases of tuberculosis in persons with HIV in 2011.⁷⁸ Almost 80% of these cases were in residents of sub-Saharan Africa.⁷⁸ There are also approximately 11 million HIV-infected individuals with latent tuberculosis.⁷⁸ More than 400,000 HIV-infected persons died of tuberculosis in 2011, making it the leading cause of death in HIV-infected populations worldwide.⁷⁸

The AIDS epidemic has also affected tuberculosis in the United States. Before 1985, the incidence of tuberculosis in the United States regularly declined by 5% to 6% per year. From 1985 through 1992, tuberculosis cases increased by 20%, which resulted in 51,700 additional cases of tuberculosis being reported in excess of that predicted by the annual decline previously noted.⁷⁹ Since 1992, tuberculosis cases have decreased again. Indeed, in 2012, fewer than 10,000 cases were reported, the lowest number since tuberculosis reporting began in 1953.⁸⁰ The proportion of tuberculosis cases with known HIV infection has also decreased from 15% in 2003 to 7.7% in 2012.⁸⁰

It remains unclear whether HIV-infected persons are more likely to acquire tuberculous infection after exposure to *M. tuberculosis* than non-HIV-infected persons. Once an individual becomes infected, however, there is no doubt that HIV infection increases the risk for development of primary tuberculosis as well as progressing from *latent tuberculosis infection* (LTBI) to active tuberculous disease. Instead of a 5% lifetime risk of disease, the risk for tuberculosis among HIV-infected persons with LTBI in the pre-combination ART era has been estimated to be as high as 10% per year.

Multidrug-resistant tuberculosis (MDR-TB), defined as resistance to at least isoniazid and rifampin (also known as rifampicin in many countries), poses a particularly grim prospect for the HIV-infected person. The risk of drug-resistant tuberculosis has been reported to be greater among HIV-infected patients than among others, and drug-resistant tuberculosis appears to be associated with decreased survival, particularly in those with lower CD4⁺ cell counts or in individuals not receiving ART.⁸¹⁻⁸³ In a multivariate analysis, HIV infection was found to be an independent risk factor for isoniazid resistance, for both isoniazid and rifampin resistance, and especially for rifampin monoresistance.⁸⁴ A meta-analysis of risk factors for MDR-TB in Europe found that HIV was an independent risk factor (odds ratio, 3.52).⁸⁵ In addition, HIV-infected patients treated with intermittent rifabutin-based therapy have been found to have a high risk for acquired rifamycin resistance, including monoresistance, particularly if their CD4⁺ lymphocyte counts are less than 100 cells/ μ L.⁸⁶ Factors that lead to acquired drug resistance include an inadequate

initial treatment regimen, patient nonadherence with the prescribed regimen, and the addition of a single drug to a failing regimen. Studies using restriction fragment length polymorphism analysis have shown that MDR-TB can also develop as a result of exogenous reinfection from a multidrug-resistant source.⁸⁷

Extensively drug-resistant tuberculosis (XDR-TB), defined as resistance to at least isoniazid and rifampin (i.e., MDR-TB), plus resistance to any fluoroquinolone and at least one second-line injectable drug, was first reported in 2006.⁸⁸ It has been documented in all regions of the world and in HIV-infected persons.⁸⁹⁻⁹¹ The true extent of XDR-TB is unknown because many laboratories worldwide are unable to perform susceptibility tests, particularly to second-line drugs, and rely only on smear results for diagnosing tuberculosis. A case series of 53 persons with XDR-TB in South Africa found that, of the 44 patients who underwent HIV testing, all were HIV infected; 52 of the 53 patients died, and the median survival was only 16 days.⁹² Epidemiologic evidence strongly suggested that the outbreak of XDR-TB was a result of person-to-person transmission, especially in a nosocomial setting.

Clinical Features. Worldwide, tuberculosis is the most common initial manifestation of underlying HIV infection.⁹³ The clinical and radiographic features of tuberculosis in both HIV-infected and non-HIV-infected persons vary and are fully discussed in Chapter 35. HIV infection is independently associated with an increased risk for extrapulmonary tuberculosis.⁹⁴ HIV infection is also associated with a lower frequency of cavitary tuberculosis, especially in patients with fewer than 200 CD4⁺ T lymphocytes/ μ L at the time of tuberculosis diagnosis.⁹⁵

CD4⁺ Lymphocyte Count. Tuberculosis may develop throughout the course of HIV infection, regardless of the CD4⁺ lymphocyte count, but the incidence of tuberculosis increases as the count decreases. Tuberculosis is much less common in patients receiving ART, but can still happen. The clinical expression of tuberculosis in HIV-infected persons is largely dependent on the degree of host immunosuppression, as indicated by the CD4⁺ lymphocyte count (Table 90-2). HIV-infected persons with early HIV disease typically present with a picture suggestive of reactivation tuberculosis, with disease usually limited to the lungs. In contrast, persons with more advanced HIV disease typically

Table 90-2 Manifestations of HIV-Related Tuberculosis in “Early” and “Late” HIV Infection

Feature	Early HIV	Late HIV
Extrapulmonary	10-15%	>50%
Radiographic distribution	Upper zones	Lower and middle zones
Radiographic findings		
Cavitation	Common	Uncommon
Adenopathy	Uncommon	Common
Miliary	Uncommon	Common
Pleural effusion	Uncommon	Rare

Figure 90-2 Tuberculosis. Frontal chest radiograph of an HIV-infected patient showing focal right lung consolidation with air bronchograms. Culture of sputum revealed *Mycobacterium tuberculosis* that was monorifampin resistant. Knowledge of the patient's CD4⁺ lymphocyte count (<50 cells/μL) and understanding that tuberculosis can present with middle to lower lung zone consolidation during "late" HIV infection were instrumental in making the diagnosis of tuberculosis. The key was in the patient's pocket. (Courtesy L. Huang.)

present with a picture reminiscent of primary pulmonary tuberculosis, often with disseminated or extrapulmonary tuberculosis. In a series of 97 HIV-infected patients with tuberculosis, Jones and colleagues⁹⁶ reported that extrapulmonary tuberculosis was seen in 30 of 43 patients (70%) with a CD4⁺ lymphocyte count of 100 cells/μL or fewer, in 10 of 20 patients (50%) with a count between 101 and 200 cells/μL, in 7 of 16 patients (44%) with a count between 201 and 300 cells/μL, and in only 5 of 18 patients (28%) with a count greater than 300 cells/μL. Virtually any extrapulmonary site may be involved; common sites include lymph nodes (usually cervical, supraclavicular, and axillary), bone marrow, genitourinary tract, central nervous system, and liver.⁹⁷

Imaging. The prevalence of specific chest radiograph features of tuberculosis also depends on the degree of host immunosuppression. Early in the course of HIV infection, tuberculosis mirrors that encountered in immunocompetent persons: upper lung zone opacities, often with cavitation, on chest radiograph. However, later in the course of HIV infection, tuberculosis often presents with middle and lower lung zone opacities (Fig. 90-2, eFig. 90-3); with diffuse opacities, including a miliary pattern (eFig. 90-4); or with a normal chest radiograph. As the CD4⁺ lymphocyte count declines, cavitation becomes less common⁹⁵ and intrathoracic adenopathy (Fig. 90-3, eFig. 90-5) becomes more common. Jones and colleagues⁹⁶ reported that adenopathy was seen on the radiographs of 20 of 58 HIV-infected patients (34%) with a CD4⁺ lymphocyte count of 200 cells/μL or fewer compared with 4 of 29 patients (14%) with a CD4⁺ lymphocyte count greater than 200 cells/μL ($P = 0.04$). ART also affects the chest radiographic appearance in HIV-infected patients with tuberculosis; in one study of 209 patients, 82% of patients receiving ART presented with

Figure 90-3 Tuberculosis. Frontal chest radiograph of an HIV-infected patient showing mediastinal adenopathy. Culture of biopsy material revealed *Mycobacterium tuberculosis*. Among HIV-infected persons, the proportion of cases that present with intrathoracic adenopathy on chest radiograph increases as the CD4⁺ lymphocyte count decreases. (From Murray JF, Mills J: Pulmonary complications of HIV infection. *Am Rev Respir Dis* 141:1356–1372, 1582–1598, 1990.)

a radiographic pattern of tuberculosis resembling that in immunocompetent persons, compared with 44% of patients not receiving ART ($P < 0.001$).⁹⁸

Diagnosis. The diagnostic approach to tuberculosis is the same for HIV-infected as for non-HIV-infected persons, with the "gold standard" diagnostic test being isolation and identification of *M. tuberculosis* by culture or by nucleic acid amplification (Chapter 35). Three sputum specimens should be examined for AFB and cultured for mycobacteria.²⁹ Current recommendations support the use of nucleic acid amplification testing of at least one sputum specimen because these tests can confirm the presence of tuberculosis or another mycobacteria in smear-positive patients and because nucleic acid amplification testing is more sensitive than AFB smear, allowing more rapid identification of smear-negative, culture-positive samples.^{29,99-101} In patients with a nonproductive cough or scant secretions, sputum induction should be performed. Virtually any specimen can be studied for mycobacteria, including sputum, pleural fluid, urine, cerebrospinal fluid, and BAL fluid; Wang needle, fine-needle, and bone marrow aspirates; and all biopsy and tissue specimens. The sensitivity of mycobacterial culture of induced sputum for HIV-infected patients with pleural effusions due to tuberculosis has been reported to be as high as 77%, and cultures of samples from extrapulmonary sites have a higher sensitivity in those with advanced immunodeficiency.¹⁰² Blood cultures are specific and should be obtained, especially from those persons with a CD4⁺ lymphocyte count less than 200 cells/μL.

All cultures positive for *M. tuberculosis* should be submitted for susceptibility testing, because the results are essential in identifying cases of drug resistance and in tailoring definitive treatment. More rapid identification of drug-resistance may be possible with genotypic testing to identify

drug-resistance mutations in places where these tests are available.^{29,99,100,103}

Treatment. The treatment of patients with tuberculosis is similar for HIV-infected and non-HIV-infected persons (Chapter 35).²⁹ Because tuberculosis is transmissible, persons with suspected tuberculosis should be started promptly on empirical antituberculosis treatment to reduce the risk of transmission. The detection of AFB on smear or in culture, regardless of the source, is an indication for empirical antituberculosis treatment until final identification is obtained. HIV-infected persons with suspected tuberculosis should be started on four antituberculous drugs: isoniazid, rifampin, pyrazinamide, and ethambutol along with pyridoxine.^{29,104} Directly observed therapy is recommended.²⁹ If resistance to rifampin is suspected or confirmed, moxifloxacin or levofloxacin and an aminoglycoside or capreomycin should be included in the initial regimen and a tuberculosis expert consulted.²⁹ When results of species identification and susceptibility testing become available, treatment can be tailored as needed. In the United States, the response to tuberculosis therapy and the time to convert sputum cultures from positive to negative appear to be similar in HIV-infected and non-HIV-infected patients.¹⁰⁴ In sub-Saharan Africa, however, the likelihood of death, especially during the first 2 months of therapy, and of relapse following apparently successful treatment is considerably higher in HIV-infected than in non-HIV-infected patients.¹⁰⁵

HIV-infected patients with tuberculosis are more likely to experience toxicity from antituberculous drugs than are non-HIV-infected persons. One series found that 40% of HIV-infected persons suffered serious adverse events from antituberculous drugs compared with 26% of non-HIV-infected persons ($P = 0.008$).¹⁰⁶ HIV-infected patients are frequently receiving a number of additional medications, and it is often difficult to distinguish an adverse drug effect to antituberculous drugs from adverse effects to these other medications. As a result, the first-line antituberculous drugs (especially isoniazid and rifampin) should only be discontinued permanently if there is strong evidence that these medications were the cause.¹⁰⁴

Despite challenges in ART use during TB therapy, as described later, ART given concurrently with tuberculosis treatment rather than sequentially has been associated with decreased mortality, greater AIDS-free survival, and more rapid conversion of sputum smears and culture in randomized studies.^{29,107-111} Thus, all HIV-infected individuals with TB should receive ART.²⁹ If the patient is naive to ART, it is recommended that ART be initiated within 2 weeks of tuberculosis treatment initiation in individuals with CD4⁺ cell counts less than 50 cells/ μ L and within 8 to 12 weeks in all others.²⁹ Individuals receiving ART should continue its use during TB therapy.

Clinicians need to be aware of several challenges of ART use during TB treatment. HIV-infected patients with tuberculosis who begin therapy for both *M. tuberculosis* and HIV infection may develop *immune reconstitution inflammatory syndrome* (IRIS), a paradoxical reaction presenting as a temporary exacerbation of clinical and radiographic features, which is more common with ART started early during antituberculosis therapy and among those with disseminated

tuberculosis.¹⁰⁸⁻¹¹² Furthermore, simultaneous treatment of HIV and *M. tuberculosis* poses additional challenges in terms of drug interactions. Both HIV *protease inhibitors* (PIs) and *non-nucleoside reverse transcriptase inhibitors* (NNRTIs) have significant interactions with the rifamycins, principally related to the induction or inhibition (or both) of the hepatic *cytochrome P-450* (CYP) enzyme system.¹⁰⁴ Decreased drug levels are associated with development of drug resistance by both HIV and *M. tuberculosis*, whereas increased drug levels are correlated with toxicity. In persons receiving PIs, rifabutin is preferred over rifampin because it is a less potent CYP 3A4 inducer. Information on the interactions between specific antiretroviral drugs and different rifamycins is regularly updated and can be found on such websites as the CDC website <http://www.cdc.gov/tb>. Clinicians caring for HIV-infected patients with tuberculosis should consult experts for aid in management prior to initiating tuberculosis or HIV therapy.

Prevention of Exposure. In hospitals and health care facilities, all persons with HIV infection and signs or symptoms compatible with tuberculosis should be placed in respiratory isolation until three sputum smears are negative. Prevention of transmission of drug-resistant tuberculosis is particularly important, for those with and without HIV infection. In a modeling study, measures such as improved ventilation, rapid drug sensitivity testing, HIV treatment, and tuberculosis isolation facilities were found to be effective preventive measures, but involuntary detention for XDR-TB treatment was thought to lead to an increase in transmission. This study also estimated that mask use and a shift to outpatient therapy could prevent about one third of XDR-TB cases in a highly prevalent area.¹¹³ A subsequent randomized study of patient mask use demonstrated a 56% decrease in TB transmission.^{29,114}

Prevention of Disease. HIV-infected persons are at a high risk for progressing from LTBI to active tuberculosis. Therefore, HIV-infected persons should be tested for LTBI by either a tuberculin skin test or *interferon- γ* (IFN- γ) release assay when HIV infection is first identified.^{29,115} HIV-infected persons who are at risk for exposure to *M. tuberculosis* (either ongoing or repeated) should be tested for LTBI annually.²⁹ In addition, persons who initially had a negative test, but subsequently experienced an increase in their CD4⁺ lymphocyte count to ≥ 200 cells/ μ L due to ART should be retested for LTBI.²⁹ Any individual with a positive test for LTBI should be screened for symptoms and chest radiographic findings suggestive of active TB.²⁹

Several studies document that the risk of LTBI reactivation is virtually eliminated if an HIV-infected person who has been infected with a drug-susceptible organism takes adequate prophylaxis.^{29,115-117} HIV-infected persons with a positive tuberculin skin reaction (defined as 5-mm induration or greater), a positive IFN- γ release assay, or with a history of either of these and who have not received prior treatment for either LTBI or active tuberculosis should receive prophylaxis. HIV-infected individuals who are close contacts of anyone with active TB should also receive prophylactic therapy.²⁹ The standard prophylaxis treatment is isoniazid (300 mg daily or 900 mg twice weekly) plus pyridoxine for 9 months.²⁹ An alternative treatment for LTBI is

rifampin daily for 4 months. The two-drug regimen of rifampin plus pyrazinamide for 2 months is no longer recommended due to an increased incidence of severe hepatotoxicity and death. Although a 12-week regimen of high-dose isoniazid and rifapentine by weekly directly observed therapy is another alternative,¹¹⁸ this regimen is not recommended for HIV-infected patients who are on ART due to drug interactions between certain antiretrovirals and rifapentine. Expert consultation should be sought for patients receiving ART or for individuals exposed to drug-resistant tuberculosis. Routine use of preventive therapy in anergic or purified protein derivative–negative HIV-infected persons is not generally recommended.^{29,115}

Mycobacterium avium Complex

As discussed in Chapter 36, MAC consists of several related *Mycobacterium* species, including *M. avium* and *M. intracellulare*. Until 1980, only 24 cases of disseminated MAC had been reported.¹¹⁹ Coincident with the onset of the AIDS epidemic, the number of cases rose dramatically. With the use of ART, however, the incidence of disseminated MAC has declined since 1996.¹

The pathogenesis of disseminated MAC is incompletely understood, but it is believed to result from primary acquisition of the microorganism, which is ubiquitous in the environment, rather than reactivation of latent infection.¹²⁰ These mycobacteria probably enter the body chiefly through the gastrointestinal tract and occasionally through the lungs.¹²¹ Person-to-person transmission is believed to be uncommon. Nearly all cases of disseminated MAC are caused by *M. avium* serotypes, which suggests that there are important differences in exposure to or virulence of these particular strains.

Clinical Features. Although the lungs are an important potential portal of entry for MAC into the bloodstream, isolated MAC pulmonary disease is rare in the context of AIDS.¹²² The most common clinical presentation of disseminated MAC disease is a febrile wasting syndrome consisting of fever, night sweats, fatigue, anorexia, and weight loss; other manifestations include abdominal pain and chronic diarrhea, hepatosplenomegaly, lymphadenopathy, progressive anemia, and, rarely, extrabiliary obstructive jaundice.¹²³ Laboratory abnormalities include anemia, which is often severe, and an elevated alkaline phosphatase level.

CD4⁺ Lymphocyte Count. More than 95% of cases of disseminated MAC are seen in HIV-infected patients whose CD4⁺ lymphocyte count is 50 cells/ μ L or less.¹²³ Other risk factors for disseminated MAC include a plasma HIV viral level greater than 100,000 copies/mL, history of previous opportunistic infection, and previous MAC colonization of the respiratory or gastrointestinal tract.²⁹

Imaging. The chest radiograph is typically normal, even when the organism is cultured from respiratory tract secretions.¹²¹ Focal pneumonia has been reported (eFig. 90-6) but is extremely rare,¹²² as is presentation as a solitary pulmonary nodule (eFig. 90-7). More frequently seen—but still uncommon—are endobronchial lesions without pneumonia.¹²⁴ These endobronchial lesions appear to be

submucosal “pearls” (eFig. 90-8) that are teeming with AFB on biopsy. Lymphadenopathy—with or without necrosis—is one of the more common imaging manifestations of thoracic MAC infection in HIV-infected patients (eFig. 90-9). Many of the cases of isolated pulmonary MAC were reported in patients who received ART, thus raising the possibility that this particular manifestation is an example of immune reconstitution. Clinicians should be aware of this possibility when starting patients on ART because IRIS may be seen either in patients with diagnosed disease or in those with subclinical infection.

Diagnosis. In HIV-infected patients with MAC, the organism can be cultured from numerous sites, but the most productive sources are blood, bone marrow, liver, or lymph nodes.¹²³ The sensitivity of blood cultures for disseminated MAC has ranged from 86% to 98% of cases in which disseminated disease was confirmed by autopsy. The diagnosis of disseminated MAC can also be established by cultures from any normally sterile body site. Often, MAC is cultured from respiratory specimens such as sputum or BAL fluid but, depending on the clinical situation, this finding may not indicate either pulmonary or disseminated disease.^{121,125} If patients have abnormal chest radiographs with positive sputum cultures, the diagnostic criteria for nonimmunosuppressed hosts recommended by the *American Thoracic Society and the Infectious Disease Society of America* (ATS/IDSA), listed in Table 36-3, should be applied.¹²⁵ The pathologic findings of MAC infection are characteristic, but not definitive; AFBs are remarkably abundant and are often packed within foamy macrophages or histiocytes; granulomas are usually absent or poorly formed.

Treatment. As emphasized in Chapter 36, the key to any regimen is the use of at least two drugs including a macrolide: clarithromycin (500 mg twice daily) is preferred, but azithromycin (500 to 600 mg daily) can be substituted if needed.²⁹ One of these should be combined with ethambutol (15 mg/kg/day). Use of a third or fourth agent such as rifabutin (300 mg daily), an aminoglycoside (i.e., amikacin 10 to 15 mg/kg intravenously daily), or a fluoroquinolone (i.e., levofloxacin 500 mg daily) can be considered in patients with advanced immunosuppression, high mycobacterial burden, or the inability to take ART.²⁹ As with tuberculosis, the use of rifabutin must be carefully scrutinized with concurrent administration of an NNRTI or a PI.

Prevention of Exposure. Although MAC can be found in environmental sources such as food and water, there are no specific recommendations regarding exposure avoidance as a prevention strategy.²⁹ Similarly, although the presence of MAC in a stool or respiratory specimen is predictive of disseminated disease, routine screening of either is not recommended.

Prevention of Disease. The CDC, NIH, and HIVMA/IDSA guidelines recommend that MAC prophylaxis be administered to HIV-infected patients with a CD4⁺ lymphocyte count less than 50 cells/ μ L and no clinical evidence of disseminated MAC.²⁹ Preferred MAC prophylaxis regimens include azithromycin (1200 mg weekly or 600 mg twice weekly) or clarithromycin (500 mg twice daily). Rifabutin

(300 mg daily) is an alternative regimen if patients are intolerant of azithromycin or clarithromycin.²⁹ If rifabutin is to be used, tuberculosis must first be ruled out, because its use for MAC has been associated with rifampin monoresistance in *M. tuberculosis*. Primary MAC prophylaxis should be discontinued in persons who have experienced a significant response to ART with an increase in their CD4⁺ lymphocyte count to greater than 100 cells/ μ L for at least 3 months.²⁹ Individuals with a history of disseminated MAC should receive secondary prophylaxis/chronic maintenance therapy with a MAC treatment regimen cited earlier. In the setting of ART with increases in the CD4⁺ lymphocyte count to more than 100 cells/ μ L for at least 6 months—and after a minimum of 12 months of a macrolide-based MAC treatment regimen—most patients can discontinue therapy without relapse.²⁹

Mycobacterium kansasii

As described in Chapter 36, *M. kansasii* has a particular geographic distribution, predominantly in the southern and central United States.¹²⁵ Clusters of disease have also been reported in Europe, Asia, and Africa. Before the AIDS epidemic, infection and disease due to *M. kansasii* were uncommon; thereafter, a dramatic increase in the incidence associated with HIV infection was observed, even in areas where *M. kansasii* was not thought to be endemic. Bloch and associates¹²⁶ found a cumulative incidence of *M. kansasii* infection of 2.4 cases per 100,000 HIV-infected adults in three counties in northern California, a rate that is almost five times higher than the national rate. Although *M. kansasii* pulmonary disease can be clinically indistinguishable from tuberculosis,¹²⁷ person-to-person transmission has not been documented, and infection is thought to arise from environmental sources.

CD4⁺ Lymphocyte Count. Similar to tuberculosis in HIV-infected persons, *M. kansasii* pneumonia can develop at any CD4⁺ lymphocyte count. Most HIV-infected patients with *M. kansasii*, however, have evidence of severe immunosuppression with CD4⁺ lymphocyte counts typically less than 100 cells/ μ L.¹²⁶⁻¹²⁸ In a study from the ART era, Canueto-Quintero and colleagues¹²⁷ reported a mean CD4⁺ lymphocyte count of 20 cells/ μ L among 25 HIV-infected patients with *M. kansasii*. Witzig and coworkers¹²⁸ found that 32 of 49 HIV-infected patients (65%) with *M. kansasii* had isolated pulmonary disease (mean CD4⁺ lymphocyte count, 75 cells/ μ L), whereas the remainder had disseminated disease (mean CD4⁺ lymphocyte count, 28 cells/ μ L).

Imaging. The chest radiographic findings of *M. kansasii* are varied. The most common radiographic findings resemble tuberculosis and include alveolar opacities, diffuse opacities, and cavities (see Fig. 36-5; eFig. 90-10); masses, intrathoracic adenopathy, and pleural effusions have also been reported. In a series of 83 HIV-infected patients with *M. kansasii*, the most frequent findings were consolidation (66%) and nodules (42%); abnormalities were most often located in the mid-lung and lower lung zones (89%), and in 10%, radiographs were normal.¹²⁹

Diagnosis. The diagnosis of *M. kansasii* rests on its isolation and subsequent identification by culture. Pulmonary

disease can be diagnosed by all of the techniques used for the diagnosis of tuberculosis. Unlike tuberculosis, however, in which identification of *M. tuberculosis* is diagnostic of disease, the identification of *M. kansasii* can occasionally represent colonization rather than disease.¹³⁰ As previously mentioned, the ATS/IDSA guidelines have defined criteria for diagnosis of nontuberculous mycobacterial pulmonary disease that includes *M. kansasii* (see Table 36-3).¹²⁵ In addition, the use of subtyping defined by PCR-restriction enzyme analysis of the *hsp65* gene may help distinguish pathogenic from nonpathogenic isolates.¹³¹

Treatment. The recommended regimen for treatment of *M. kansasii* pulmonary disease consists of isoniazid (300 mg daily), rifampin (600 mg daily), and ethambutol (15 mg/kg daily).¹²⁵ Patients should also receive pyridoxine (50 mg daily) during treatment. Patients who take PI or NNRTI therapy for HIV infection should receive rifabutin or clarithromycin in place of rifampin. Pyrazinamide is unacceptable as an alternative drug because all *M. kansasii* isolates are resistant. Patients should receive treatment for a minimum of 12 months after their cultures become negative.

Prevention. There are no recommended prevention strategies for *M. kansasii*.

Other Mycobacteria

MAC and *M. kansasii* account for the great majority of nontuberculous mycobacterial infections complicating HIV disease. Other mycobacteria, however, have occasionally been identified.^{123,132} Increased frequency of exposure or specific defects in host defenses might account for the predominance of MAC and *M. kansasii* over other nontuberculous mycobacteria in AIDS patients; differences in the virulence of the various mycobacterial species are also likely to play an important role.

FUNGI

Early in the AIDS epidemic, fungi were recognized as major sources of morbidity and mortality. Despite the overall decline in HIV-associated opportunistic infections in the United States, fungi remain important causes of disease. Several fungi can cause pulmonary disease in HIV-infected persons.¹³³ *Pneumocystis jirovecii*, formerly *Pneumocystis carinii*, previously classified as a protozoan but currently considered a fungus, remains the most common AIDS-defining opportunistic infection in the United States and Western Europe and is a common cause of HIV-associated pneumonia. *Cryptococcus neoformans*, the most common cause of meningitis in HIV-infected persons, often presents with an associated pneumonia. The endemic fungi *H. capsulatum*, *C. immitis*, *Penicillium marneffei*, and, to a lesser extent, *Blastomyces dermatitidis* are among the chief causes of HIV-associated disease seen in their particular geographic regions, and all have important pulmonary presentations. Finally, invasive aspergillosis is often a devastating pulmonary disease seen in HIV-infected persons with severe immunodeficiency. Further information about fungal pulmonary diseases is provided in Chapters 37 and 38.

Pneumocystis jirovecii

PCP (shorthand for *Pneumocystis pneumonia*) remains the most common AIDS-defining opportunistic infection in the United States, even though its overall incidence has declined substantially.¹ Early in the AIDS epidemic, PCP accounted for nearly two thirds of AIDS-defining diagnoses, and PCP developed in an additional 15% to 20% of patients at some time during their HIV disease. Two factors—the use of ART and *Pneumocystis* prophylaxis—have dramatically reduced the overall number of cases. Nevertheless, PCP remains a risk, chiefly among persons who are unaware of their HIV infection, those who fail to seek medical care, and those who fail to adhere to or respond to ART or *Pneumocystis* prophylaxis.¹³⁴⁻¹³⁶ Recent reports of increased PCP cases in immunosuppressed non-HIV populations have unclear implications for HIV-infected populations.^{137,138}

History and Epidemiology. First identified early in the 20th century by Chagas, *Pneumocystis* was initially recognized as a human pathogen in the 1940s and 1950s. Despite more than a century of experience, several gaps in our understanding of this omnipresent organism remain.¹³⁹⁻¹⁴² One major obstacle that has impeded further advances has been the inability to culture *Pneumocystis* in vitro. Although mammals are the only known hosts of *Pneumocystis* and a number of mammals are susceptible to infection, *Pneumocystis* has been demonstrated to be species-specific.¹⁴³ Although *Pneumocystis* can be easily transmitted between mammals of the same species, animal studies that have attempted to transmit *Pneumocystis* from one species to another have been unsuccessful.¹⁴³ In recognition of the host-species specificity of *Pneumocystis*, the *Pneumocystis* that causes *Pneumocystis pneumonia* in humans is now referred to as *P. jirovecii*, in honor of Otto Jirovec, the parasitologist who is credited with first identifying *Pneumocystis* as the cause of pulmonary disease in humans.^{144,145}

The precise ecologic niche for *P. jirovecii* and its mode of transmission is unknown.^{141,146} The inability to maintain human *Pneumocystis* in culture suggests that *P. jirovecii* may be unable to grow outside of its human host. Given its species specificity, it is doubtful that other mammals are the reservoir for *P. jirovecii*. This host-species specificity also implies coevolution of humans and *P. jirovecii* that, in turn, implies long-term carriage of *P. jirovecii* in its human host. Infection with *P. jirovecii* is almost ubiquitous. Up to 85% to 100% of the U.S. population have specific antibodies directed against *P. jirovecii* by the age of 3 years.^{147,148} Clearly, PCP never develops in most of these individuals. In the setting of severe immunosuppression, however, PCP can affect significant proportions of people. These studies and others suggest that reactivation of latent infection is a cause of *P. jirovecii* disease among immunocompromised hosts. Outbreaks of newly acquired infection after de novo exposure to persons with PCP have also been documented among immunocompromised patients in pediatric wards, cancer clinics or wards, transplantation units, and other confined spaces, which suggests person-to-person transmission of *P. jirovecii* and the rapid development of disease. Results of studies that have used molecular tools to detect *Pneumocystis* are consistent with transmission of *P. jirovecii* from patients with PCP to their household and hospital con-

tacts,^{149,150} probably via inhalation of a *Pneumocystis*-containing aerosol.^{151,152}

Risk Factors. Traditional risk factors for the development of PCP among HIV-infected adults include a CD4⁺ lymphocyte count less than 200 cells/μL, a history of PCP, and oropharyngeal candidiasis.^{153,154} In the current ART era, HIV-infected persons with a CD4⁺ lymphocyte count between 101 and 200 cells/μL, but a suppressed HIV RNA level on ART appear to be at low risk for primary PCP.^{155,156}

CD4⁺ Lymphocyte Count. Approximately 95% of adolescent and adult cases of PCP are seen in HIV-infected patients whose CD4⁺ lymphocyte count is less than 200 cells/μL.¹⁵⁴ The Multicenter AIDS Cohort Study found a markedly increased risk for PCP among HIV-infected subjects with a CD4⁺ lymphocyte count of 200 cells/μL or fewer at study entry.¹⁵³ These subjects had a nearly fivefold greater risk of developing PCP than did subjects who had a CD4⁺ lymphocyte count higher than 200 cells/μL at study entry. This study also demonstrated that the presence of fever for 2 weeks or more and the development of thrush were independent predictors for PCP. Stansell and colleagues¹⁵⁴ found that the incidence of PCP increased as the CD4⁺ lymphocyte count declined. Subjects with a CD4⁺ lymphocyte count between 101 and 200 cells/μL had an incidence of 5.95 cases of PCP per 100 person-years, whereas those with a CD4⁺ lymphocyte count of 100 cells/μL or fewer had 11.13 cases per 100 person-years. In persons on ART, the most recent CD4⁺ lymphocyte count is generally a better indicator of an HIV-infected person's risk for PCP than their nadir CD4⁺ lymphocyte count.

Clinical Features. HIV-infected adults, unlike other immunocompromised persons, usually have a prolonged prodromal illness associated with PCP. Kovacs and coworkers¹⁵⁷ found the median duration of symptoms in 40 HIV-infected patients was 28 days, which was significantly longer than the median duration of 5 days seen in 37 patients with other underlying conditions ($P < 0.0002$). Kales and colleagues¹⁵⁸ reported a median duration of symptoms of 3 weeks in 145 HIV-infected patients with PCP and found that 72 patients (50%) had a duration of symptoms of 2 weeks or longer. This duration of symptoms can often be used to distinguish PCP from pyogenic pneumonia, which typically presents with 3 to 5 days of symptoms.

Classically, PCP presents with fever, a nonproductive cough, and dyspnea on exertion. Fever was noted in 86%, cough in 91%, and dyspnea in 95% in one series of 145 HIV-infected patients with PCP.¹⁵⁸ High temperature, rigors, purulent sputum, and pleuritic chest pain are uncommon and can be used to distinguish PCP from pyogenic pneumonia. In a multivariable analysis, Selwyn and associates¹⁵⁹ found that the presence of purulent sputum was an independent predictor of bacterial pneumonia, rather than of PCP or tuberculosis.

Physical examination of the chest may be normal. In the series reported by Kales and colleagues,¹⁵⁸ 78 patients (54%) with PCP had a normal lung examination. When abnormal, the most frequent findings on lung auscultation are inspiratory crackles, which have been reported to be

Figure 90-4 *Pneumocystis pneumonia*. Frontal chest radiograph of an HIV-infected patient with *Pneumocystis pneumonia* showing bilateral, predominantly perihilar, granular opacities and three pneumatoceles (arrows). Pneumatoceles may be single or multiple in number, and small or large in size, and may predispose patients to pneumothorax. (Courtesy L. Huang.)

associated with a greater disease severity and an increased mortality.¹⁵⁸ Oxygen desaturation with exertion is a sensitive but nonspecific indicator of PCP.

Numerous studies have shown that the serum *lactate dehydrogenase* (LDH) level is increased in patients with PCP; however, an elevated serum LDH level does not establish the diagnosis of PCP, nor does a normal serum LDH value rule out the diagnosis. Serum *S*-adenosylmethionine concentration¹⁶⁰ and β -D-glucan,^{161,162} have also been reported to be potential diagnostic tools for PCP.

Imaging. Classically, PCP presents with bilateral, symmetrical reticular opacities, often manifesting as peribronchovascular indistinctness (eFig. 90-11), or as granular or a ground-glass appearance (eFig. 90-12A);¹⁶³ these opacities typically begin in the perihilar region and extend outward as the disease severity increases. The ground-glass opacity appearance is particularly associated with the chest CT manifestations of this disorder (see eFig. 90-12B). Occasionally, the opacities are unilateral or asymmetrical (eFig. 90-13); a lobar or focal radiographic pattern is uncommon. Thin-walled cysts, or pneumatoceles, are seen in 10% to 20% of cases (Fig. 90-4).¹⁶⁴ Pneumatoceles may be present at the time of diagnosis or may develop during PCP therapy. Pneumatoceles may be single (eFig. 90-14A) or multiple (eFig. 90-14B-D), and small or large, and predispose patients to pneumothorax (eFig. 90-15), which is another radiographic presentation of PCP. Usually pneumatoceles resolve (see eFig. 90-14B-D), but occasionally they persist despite successful therapy.

Figure 90-5 *Pneumocystis pneumonia*. Frontal chest radiograph of an HIV-infected patient who had been receiving aerosolized pentamidine showing reticular infiltration, predominantly of the upper lung zones, secondary to relapsed *Pneumocystis pneumonia* (PCP). This radiographic presentation, however, may also be seen in patients on no PCP prophylaxis. (From Murray JF, Mills J: Pulmonary complications of HIV infection. *Am Rev Respir Dis* 141:1356–1372, 1582–1598, 1990.)

Virtually every possible radiographic finding, including focal, lobar, or segmental consolidation (eFigs. 90-16 through 90-18), nodules (eFig. 90-19) with or without cavitation, and a miliary pattern, can be seen occasionally.¹⁶⁴ Apical or upper lung zone disease that mimics tuberculosis (Fig. 90-5, eFig. 90-20) is typically associated with aerosolized pentamidine prophylaxis, although this presentation can be seen as well in patients taking oral prophylaxis or no preventive therapy. Intrathoracic adenopathy and pleural effusions are rarely due to PCP. These radiographic findings should prompt a search for an alternate or at least a coexisting process such as bacterial pneumonia, tuberculosis, fungal pneumonia, or pulmonary KS. PCP may also present with a normal chest radiograph. Published studies report the incidence of a normal radiograph to range from 0% to 39%.¹⁶³⁻¹⁶⁵ In persons with a high clinical suspicion for PCP but a normal chest radiograph, chest high resolution CT can be useful.¹⁶⁶

Diagnosis. The diagnosis of PCP rests on the microscopic visualization of the characteristic *P. jirovecii* cysts or trophic forms (or both) on stained respiratory specimens. The standard methods for detection of *P. jirovecii* have been with cyst wall stains such as methenamine silver and toluidine blue-O or with Giemsa and Diff-Quik, which stain both the cysts and trophic forms; monoclonal antibodies to *P. jirovecii* are also used.¹⁶⁷ PCR-based techniques have also been employed and have been reported to be more sensitive but also less specific than these other methods.^{167,168}

Pneumocystis jirovecii can be detected in expectorated (infrequently) or induced sputum; in pulmonary secretions obtained by endotracheal suction, BAL, or percutaneous

aspiration of lung parenchyma; and in pulmonary tissue obtained by transbronchial, thorascopic, or open-lung biopsy. Of these, sputum induction and BAL are the most widely used. Sputum induction is an appropriate initial diagnostic procedure for PCP, but the sensitivity of induced sputum is less than 100% and thus a negative result should be followed by a more definitive procedure, namely bronchoscopy with BAL.³¹ BAL is performed in the most affected lobe visualized on chest radiograph. For patients with diffuse radiographic disease, BAL in the right middle lobe is usually performed. For patients with an upper lung zone predominance on radiograph, lavage in both an upper lobe and the right middle lobe should be considered. Despite the widespread use of TMP-SMX and dapsone for PCP prophylaxis, no studies have evaluated whether the yield of diagnostic studies is changed in persons receiving one of these medications. Clinical experience suggests that, although the severity of chest radiograph abnormalities may be milder in patients receiving prophylaxis than in those receiving no prophylaxis, the diagnostic yields from both sputum induction and BAL remain the same.

Treatment. The treatment of choice for patients with mild, moderate, and severe PCP remains TMP-SMX administered for 21 days.²⁹ TMP-SMX possesses many benefits, including availability in both an intravenous and an oral form, excellent oral bioavailability, and activity against many community-acquired bacteria that may cause concomitant pyogenic infection. The usual dose of TMP is 15 mg/kg/day (range, 15 to 20 mg/kg/day) and that of SMX is 75 mg/kg/day (range, 75 to 100 mg/kg/day), divided into three or four daily doses (Table 90-3). Dosing may be intravenous (recommended for patients with moderate or severe PCP) or oral. Unfortunately, adverse effects from TMP-SMX are frequent in HIV-infected patients and include rash, fever, gastrointestinal complaints (nausea, vomiting), elevated transaminases, hyperkalemia, and bone marrow suppression, especially anemia and neutropenia.

These effects often develop during the second week of therapy. In a significant proportion of HIV-infected patients, the side effects of TMP-SMX are ultimately treatment-limiting. Rare adverse reactions include Stevens-Johnson syndrome, toxic epidermal necrolysis, and a clinical syndrome resembling septic shock with hypotension, fever, pulmonary opacities, and renal and hepatic dysfunction. Studies are conflicting regarding the presence of potential TMP-SMX drug resistance in *Pneumocystis*.^{169,170}

For patients with an allergy to or intolerance of TMP-SMX, alternative treatment regimens (see Table 90-3) include intravenous pentamidine, clindamycin plus primaquine, trimethoprim plus dapsone, and atovaquone.²⁹ Aerosolized pentamidine should not be used for PCP treatment.²⁹ Small reports describe successful PCP treatment with echinocandins.^{171,172} Similar to tuberculosis, HIV-infected patients with PCP who begin therapy for *Pneumocystis* and initiate ART may develop paradoxical reactions, usually a temporary exacerbation of clinical and radiographic features but occasionally respiratory failure, due to immune reconstitution.^{173,174} The diagnosis of IRIS is one of exclusion. Patients with paradoxical reactions only rarely require discontinuation of antiretroviral therapies, and symptomatic therapy is recommended.

Corticosteroid Therapy. In 1990, the NIH-University of California Expert Panel for Corticosteroids as Adjunctive Therapy for *Pneumocystis* Pneumonia¹⁷⁵ concluded that adjunctive corticosteroid therapy “can clearly reduce the likelihood of death, respiratory failure, or deterioration of oxygenation in patients with moderate-to-severe *Pneumocystis* pneumonia.” The panel recommended that corticosteroids be given to adults or adolescents with documented or suspected PCP if they have an arterial PO₂ level less than 70 mm Hg or an alveolar-arterial PO₂ difference greater than 35 mm Hg. Adjunctive corticosteroids, either oral prednisone or intravenous methylprednisolone, should be started at the same time as specific anti-*Pneumocystis*

Table 90-3 Treatment Regimens for *Pneumocystis* Pneumonia*

Treatment Regimen	Dose(s), Frequency	Toxicities
MILD PCP[†] (PaO₂ >70 mm Hg AND ALVEOLAR-ARTERIAL O₂ DIFFERENCE <35 mm Hg)		
Trimethoprim-sulfamethoxazole (TMP-SMX)	15-20 mg/kg (TMP component) daily (q 6-8 hours)	Fever, dermatologic, gastrointestinal, hematologic
Trimethoprim plus Dapsone	15-20 mg/kg daily (q 6-8 hours) 100 mg once daily	Dermatologic, gastrointestinal, hematologic
Clindamycin plus Primaquine	1800 mg daily (q 6-8 hours) 30 mg (base) once daily	Dermatologic, gastrointestinal, hematologic
Atovaquone	750 mg thrice daily	Dermatologic, gastrointestinal
MODERATE-SEVERE PCP[‡] (PaO₂ ≤70 mm Hg OR ALVEOLAR-ARTERIAL O₂ DIFFERENCE ≥35 mm Hg)		
Trimethoprim-sulfamethoxazole (TMP-SMX)	15-20 mg/kg (TMP component) daily (q 6-8 hours)	Fever, dermatologic, gastrointestinal, hematologic
Pentamidine	3-4 mg/kg IV once daily	Renal, pancreatic
Clindamycin plus Primaquine	1800-2400 mg (q 6-8 hours) 30 mg (base) once daily	Dermatologic, gastrointestinal, hematologic

*Recommended duration of therapy = 21 days.

[†]Oral route is preferred for patients with mild *Pneumocystis* pneumonia (PCP) who are treated as outpatients.

[‡]Intravenous (IV) route is preferred (at least until clinical improvement) for patients with moderate-severe PCP. Adjunctive corticosteroids (prednisone 40 mg, PO, twice daily for 5 days, then 40 mg, PO, once daily for 5 days, then 20 mg, PO, once daily for 11 days or potency-equivalent Solu-Medrol IV) should also be administered.

treatment is begun regardless of whether the diagnosis has been confirmed.

Early in the AIDS epidemic, it was realized that acute respiratory failure secondary to PCP, if severe enough to warrant mechanical ventilation, had a mortality rate of 86% or greater.¹⁷⁵ Subsequent reports from individual hospitals confirmed this gloomy prognosis; 39 of 45 patients who were intubated and ventilated for PCP at San Francisco General Hospital from 1981 to 1985 died, a mortality rate of 87%.⁷⁷ Although the mortality associated with acute respiratory failure secondary to PCP remains significant (approximately 30% to 50%), encouraging progress has been made.^{176,177} HIV-infected patients with PCP and respiratory failure requiring mechanical ventilation should be managed with lung-protective strategies as for patients with acute respiratory distress syndrome.¹⁷⁸ At least one retrospective study by Morris and colleagues¹⁷⁶ suggests that ART may be beneficial in these cases, although prospective randomized clinical trials in the intensive care unit involving mechanically ventilated patients are lacking.^{179,180}

Prevention of Exposure. The natural reservoir for human *Pneumocystis* remains unknown.¹⁸¹ Both an environmental and a human reservoir have been suggested.^{146,182} Whether PCP results from reactivation of latent infection or also from a recent infection is debated; reports of cluster outbreaks of PCP among different immunocompromised populations support the theory that PCP can result from a recent exposure and person-to-person transmission. Accordingly, some authorities have argued that HIV-infected and other immunocompromised persons who are at risk for PCP should avoid close contact with any individuals who have PCP. However, the current CDC, NIH, and HIVMA/IDSA guidelines state “data are insufficient to support isolation as standard practice.”²⁹

Prevention of Disease. HIV-infected adults or adolescents (including those on ART) who have a CD4⁺ lymphocyte count less than 200 cells/ μ L or a history of oropharyngeal candidiasis should receive primary *Pneumocystis* prophylaxis, and persons with prior PCP should receive secondary prophylaxis (Table 90-4).²⁹ Once started, HIV-infected adults and adolescents should remain on PCP prophylaxis, unless their CD4⁺ lymphocyte counts increase from less than 200 cells/ μ L to greater than 200 cells/ μ L for at least 3 months as a result of ART; several studies have demonstrated that primary and secondary PCP prophylaxis

can be safely discontinued in the vast majority of these persons.²⁹ In rare cases, however, PCP has recurred after the discontinuation of secondary PCP prophylaxis, despite an apparent ART-associated immune reconstitution.¹⁸³

TMP-SMX, dapsone, atovaquone suspension, and aerosolized pentamidine are the standard options for PCP prophylaxis.²⁹ TMP-SMX is the first-line choice for primary and secondary prophylaxis against *Pneumocystis*. For those patients intolerant of TMP-SMX, dapsone and atovaquone are both oral drugs that can be used. Many authorities would add pyrimethamine to these drugs for patients with a history of PCP, a CD4⁺ lymphocyte count less than 100 cells/ μ L, or both. For patients who are *T. gondii* immunoglobulin G antibody positive, pyrimethamine should be added. Aerosolized pentamidine remains an effective and well-tolerated prophylaxis option; however, caution must be exercised when using this drug for secondary prophylaxis or in patients with a CD4⁺ lymphocyte count less than 100 cells/ μ L because prophylaxis break-through may be more frequent in this population.

Cryptococcus Species

Cryptococcosis is a disease caused by *C. neoformans* or *C. gattii*. Cryptococcus is the only encapsulated fungus that infects humans, either healthy or immunocompromised, and India ink or mucicarmine staining can identify its polysaccharide capsule.¹⁸⁴ *C. neoformans* and *C. gattii* can be subclassified into four serotypes, based upon capsular agglutination reactions, and two species with two varieties. *Cryptococcus* infection is transmitted after inhalation of a yeast-containing aerosol. *C. neoformans* is global in distribution, and is most commonly isolated from bird excrement, decaying fruit, and soil. Most cryptococcal disease in HIV-infected persons is due to *C. neoformans*. *Cryptococcus gattii* has been isolated from trees in Australia, as well as the Pacific Northwest of the United States and Southwestern Canada, where outbreaks of disease have been reported. *C. gattii* is more likely to infect immunocompetent hosts, although it also causes disease in HIV-infected individuals.

The incidence of cryptococcosis in HIV-infected persons has dramatically declined since the introduction of ART. In one population-based surveillance study, the annual incidence of cryptococcosis decreased from 66 per 1000 persons with AIDS in 1992 to 7 per 1000 persons in 2000 in the Atlanta area, and from 24 per 1000 persons with AIDS in 1993 to 2 per 1000 persons in 2000 in the Houston area.¹⁸⁵ Using national surveillance data, a study from

Table 90-4 Prevention of *Pneumocystis* Pneumonia

Prevention Regimens	Alternative Dosing	Comments
Trimethoprim-sulfamethoxazole 1 double-strength (DS) tablet daily Dapsone 100 mg daily	1 single-strength tablet daily or 1 DS tablet thrice weekly	Also effective prophylaxis against <i>Toxoplasma gondii</i> and many bacterial pathogens Combine with pyrimethamine and leucovorin in persons who are <i>T. gondii</i> immunoglobulin G antibody positive. Consider combining with pyrimethamine and leucovorin when used for secondary prophylaxis
Atovaquone suspension 1500 mg daily, or 750 mg twice daily		Improved bioavailability compared to tablets
Aerosolized pentamidine 300 mg monthly via RespirGard II nebulizer		May be associated with increased risk of extrapulmonary disease

France found a 46% decrease in the incidence of cryptococcosis in HIV-infected patients from the pre-combination ART period (1985-1996) to the early combination ART period (1997-2001).¹⁸⁶

Despite a declining incidence, exposure to *Cryptococcus* and cryptococcal disease is increasingly recognized in Africa and Southeast Asia. In a study from Uganda, *Cryptococcus* was isolated from 11% of BAL specimens in patients who presented with cough of greater than 2 weeks duration.¹⁸⁷ Although cryptococcal pneumonia can be a rare cause of mortality in this population,¹⁸⁸ not all cases in which *cryptococcus* was isolated were treated with antifungal therapy, raising the possibility of colonization or isolated infection.¹⁸⁷ *Cryptococcal antigen* (CRAG) testing suggests that cryptococcal infection may be more widespread than previously appreciated. In a study from Thailand of patients hospitalized with acute respiratory symptoms, 13% of HIV-infected patients compared to none of the HIV-uninfected patients had a positive CRAG test.¹⁸⁹ The proportion of HIV-infected patients with a positive CRAG in other similar studies ranged from 5% to 11%; the likelihood of a positive test increases among patients with CD4⁺ cell counts less than 100 cells/ μ L.¹⁹⁰⁻¹⁹²

Clinical Features. Although the portal of entry is the lung, cryptococcal pulmonary infection is often asymptomatic or minimally symptomatic, and the most commonly encountered manifestation of cryptococcal disease is meningitis.^{186,193,194} In a large series of 106 HIV-infected patients with cryptococcal disease, 89 patients (84%) had meningitis, and only 4 patients (4%) had isolated pneumonia.¹⁹³ In a population-based surveillance study that included 1322 HIV-infected patients with cryptococcal disease, only 45 patients (3%) had pulmonary disease in the absence of both fungemia and meningitis.¹⁸⁵ Autopsy studies suggest that pulmonary disease is underdiagnosed, particularly in settings where diagnostic facilities are limited.¹⁹⁵

When present, the most frequent respiratory complaints are cough and dyspnea.^{193,196} Pleuritic chest pain and productive cough have also been reported,¹⁹⁷ perhaps distinguishing pulmonary cryptococcosis from PCP. Although more rare, cases of acute respiratory failure have been reported.¹⁹⁵

CD4⁺ Lymphocyte Count. In most cases, cryptococcosis infects patients with a CD4⁺ lymphocyte count less than 200 cells/ μ L, and usually less than 100 cells/ μ L. A study of 1644 patients reported a median CD4⁺ count of 24 cells/ μ L with a range of 0 to 480 cells/ μ L.¹⁸⁶ A study from Uganda from the current ART era reported a median CD4⁺ count of 23 cells/ μ L.¹⁹⁸

Imaging. Cryptococcal pneumonia most commonly presents with diffuse bilateral interstitial opacities.^{197,199} In one study, Meyohas and associates²⁰⁰ reported interstitial opacities in 60 of 92 radiographs (65%) (eFig. 90-21); in addition, focal consolidation (13%) (eFig. 90-22), nodular opacities (11%) (eFig. 90-23), cavitation (11%) (Fig. 90-6), pleural effusion (14%), and hilar adenopathy (27%) (eFig. 90-24) were noted. More rarely, radiographic findings include a miliary pattern (eFig. 90-25),²⁰¹ solitary pulmonary nodules,²⁰² pulmonary masses,²⁰³ isolated pleural

Figure 90-6 Cryptococcal infection. Frontal chest radiograph of an HIV-infected patient showing a solitary cavitary lesion in the right lower lung field. Culture of bronchoalveolar lavage fluid revealed *Cryptococcus neoformans*. In HIV-infected patients, cryptococcal disease can present with a wide range of chest radiographic findings, including a normal chest radiograph. (From Stansell JD: Fungal disease in HIV-infected persons: cryptococcosis, histoplasmosis, and coccidioidomycosis. *J Thorac Imaging* 6:28-35, 1991.)

effusion,²⁰⁴ and pneumothorax.²⁰⁵ Finally, cryptococcal pneumonia may also present with a normal chest radiograph; in the review by Meyohas and associates,²⁰⁰ for example, radiograph results were normal in 11% of the 92 cases.

Diagnosis. The diagnosis of cryptococcal infection begins with the CRAG test. The test can be performed on serum, cerebrospinal fluid, urine, BAL fluid,²⁰⁶ or pleural fluid. The serum CRAG test is sensitive and specific for cryptococemia. A negative serum CRAG test virtually rules out the diagnosis of cryptococcal meningitis, but can be seen in some cases of isolated pulmonary cryptococcosis. A positive serum CRAG test should prompt an evaluation for disseminated disease, especially meningitis, but false-positive results can be seen in the presence of rheumatoid factor or infection with the fungus *Trichosporon asahii* (formerly *T. beigeli*), or with bacteria from the *Stomatococcus* or *Capnocytophaga* genera. As noted, a positive CRAG can sometimes be found in individuals without clinical evidence of disease. Blood fungal cultures are specific and should be obtained as part of the diagnostic evaluation. New cutaneous lesions may be signs of dissemination, and their sudden appearance should prompt consideration for biopsy.

The diagnosis of pulmonary cryptococcosis is usually established by culture of sputum or BAL fluid and occasionally of pleural fluid. Specimens from TBB and pleural biopsy can also be diagnostic. Batungwanayo and coworkers¹⁹⁷ found that BAL diagnosed 27 of 33 cases (sensitivity 82%) of cryptococcal pneumonia compared with TBB, which diagnosed 10 of 21 cases (sensitivity 48%). In some cases, cultures are negative, but a BAL or pleural fluid CRAG test

can establish the diagnosis.²⁰⁰ Alternatively, because the treatment is identical, the diagnosis of pneumonia may be inferred in the presence of disseminated cryptococcal disease (e.g., meningitis) and a compatible radiographic presentation. However, caution must be exercised with this approach, because other opportunistic infections such as PCP may be present concurrently and can demonstrate identical radiographic findings.

Treatment. In contrast to cryptococcal meningitis, there are no randomized controlled trials for HIV-infected patients presenting with isolated cryptococcal pneumonia or with concurrent cryptococcal pneumonia and meningitis.²⁰⁷ Some authorities would treat isolated cryptococcal pneumonia that is mild in severity with fluconazole alone (400 mg daily for 12 months) in combination with effective ART²⁰⁸; however, patients with clinically significant cryptococcal pneumonia should be considered at high risk for early deterioration and treated similarly to those with disseminated disease using the lipid formulation of amphotericin B (3 to 4 mg/kg/day) in combination with flucytosine for at least 2 weeks.²⁰⁸ Treatment should be continued until the patient is clinically improved, at which point the patient can be switched to fluconazole (400 mg daily) to complete at least an 8-week course. The patient should then be maintained on fluconazole (200 mg daily) to complete at least 12 months of azole therapy. As in patients with tuberculosis or PCP, IRIS may develop in HIV-infected patients with cryptococcosis who begin dual therapy for *C. neoformans* and HIV infection.²⁰⁹ Patients who had cryptococcal meningitis may present with aseptic meningitis and have elevated intracranial pressure. In addition, patients with cryptococcal pneumonia and nodules on chest radiograph may develop cavitation of their nodules or new intrathoracic adenopathy.²⁰⁹

Prevention. There are no specific recommendations regarding exposure avoidance or chemoprophylaxis for *C. neoformans* (e.g., fluconazole).²⁰⁸ In addition, routine screening of asymptomatic persons with serum CRAG testing is not recommended.

Histoplasma capsulatum

Histoplasmosis is a disease caused by the dimorphic, soil-dwelling fungus *H. capsulatum*. The fungus is found on all continents except Antarctica, but it is most endemic to North America and the Caribbean basin.^{184,210} The heaviest concentration is found in the Mississippi, Ohio, and St. Lawrence River valleys. In these areas, the fungus exists in microenvironments related to the enrichment of the soil with bird or bat excrement, which helps promote sporulation. In the soil, the fungus exists in a mycelial form producing asexual spores, the characteristic tuberculate macroconidia and microconidia. Microconidia are easily aerosolized when disturbed and inhalation leads to primary pulmonary infection that is usually clinically silent.

Once deposited in the alveoli, *H. capsulatum* transforms into its yeast (or parasitic) form, and an area of pneumonitis develops. During this period before cell-mediated immunity develops, the organism spreads to regional lymph nodes and to reticuloendothelial organs. Two to 3 weeks after exposure, a flulike syndrome with fever, chills, myalgias, a

nonproductive cough, and chest pain develops in about 40% of immunocompetent individuals. As emphasized in Chapter 37, 99% of these cases spontaneously resolve with the development of specific cell-mediated immunity. In contrast, progressive disseminated histoplasmosis develops in HIV-infected and other persons lacking cell-mediated immunity. Although most cases of HIV-associated histoplasmosis appear to result from de novo exposure, the disease can reactivate. These cases account for the histoplasmosis seen in nonendemic areas such as San Francisco or New York.²¹¹

Clinical Features. Although the portal of entry is the lung, in HIV-infected persons, histoplasmosis most often presents as a febrile wasting illness with disseminated infection. In a large series of 72 HIV-infected patients with disseminated histoplasmosis, 69 patients (96%) presented with fever and weight loss; in approximately 10% of cases, the presentation was dramatic with a sepsis-like syndrome associated with hypotension, respiratory failure, liver and renal failure, and coagulopathy.²¹² Prognosis in these patients is poor. Respiratory complaints at presentation, chiefly cough and dyspnea, are found in patients who are likely to have abnormal chest radiographs.^{212,213}

CD4⁺ Lymphocyte Count. Most cases of disseminated histoplasmosis are seen in patients with a CD4⁺ lymphocyte count less than 100 cells/ μ L and often less than 50 cells/ μ L. Isolated respiratory disease is more likely in patients with CD4⁺ cell counts greater than 300 cells/ μ L.²⁹ Frequent laboratory findings include anemia, leukopenia, thrombocytopenia, and liver function test elevations. Serum LDH and serum ferritin elevations, often pronounced, have also been reported.^{29,210}

Imaging. Disseminated histoplasmosis presents with a normal chest radiograph in 35% to 55% of cases.^{199,212,214} In patients with abnormal findings, the most frequent are diffuse, coarse reticular or reticulonodular opacities as shown in Figure 90-7. Occasionally, alveolar opacities are present¹⁹⁹; focal opacities are less common and seen in 7% to 11% of cases.²¹³ Hilar and mediastinal adenopathy and calcified granulomata are each found in less than 5% of patients, attesting to the low incidence of reactivation disease.²¹²

Diagnosis. The workup of histoplasmosis begins with the histoplasma antigen test, which is a sensitive method for rapid diagnosis of disease.²⁹ The antigen test can be performed on urine, serum, cerebrospinal fluid, or BAL fluid. The performance of the newer quantitative histoplasma antigen test is excellent; in AIDS patients with disseminated histoplasmosis, the antigen was detected in the urine of 100% and in the serum of 92% of patients.²¹⁵ In isolated, chronic pulmonary disease, serum or urine antigen testing is less sensitive.²⁹ In patients with pulmonary involvement, antigen testing of BAL fluid combined with cytopathology evaluation can complement serum or urine testing and increase the sensitivity for diagnosis of disease.^{29,216} With successful therapy, antigen values fall and, during relapses, antigen values rise; thus changes in antigen values can be useful for assessing response to therapy and for evaluating

Figure 90-7 Disseminated fungal infection. Frontal chest radiographic close-up of the left mid-lung of an HIV-infected patient showing a medium to coarse reticulonodular pattern characteristic of disseminated fungal disease. (From Stansell JD: Fungal disease in HIV-infected persons: cryptococcosis, histoplasmosis, and coccidioidomycosis. *J Thorac Imaging* 6:28–35, 1991.)

possible relapse.²¹⁷ A persistently positive histoplasma antigen test indicates continued disease and warrants continued therapy. False-positive histoplasma antigen test results have been seen in patients with other disseminated fungal diseases (blastomycosis, coccidioidomycosis, paracoccidioidomycosis, and penicilliosis, and rarely with aspergillosis), but such results have not been described in patients with cryptococcosis or candidiasis. Histoplasma can also be cultured from involved sites, although results may not be available for several weeks. Blood fungal cultures are specific and should be obtained as part of the diagnostic evaluation. Wheat and colleagues²¹² reported that fungal blood cultures were positive in 65 of their 72 cases (90%). Occasionally, the peripheral blood smear reveals intracellular yeast. Other potential diagnostic sources include bone marrow, lymph node, and skin. Serologic tests are generally less helpful in those with disseminated disease, but may be useful in patients who are less severely immunocompromised with isolated pulmonary disease.²⁹

Treatment. A lipid formulation of amphotericin B is the treatment of choice for HIV-infected patients with moderate to severe disseminated histoplasmosis, whereas itraconazole is an alternative for patients with mild disease.²⁹ Treatment with amphotericin B should be continued for at

least 2 weeks or until the patient is clinically improved, at which point the patient can be switched to itraconazole to complete at least a 12-month course. Patients with isolated pulmonary disease and CD4⁺ cell counts greater than 300 cells/ μ L should be treated similarly as for non-HIV-infected patients (Chapter 37).

Prevention of Exposure. In areas endemic for *H. capsulatum*, HIV-infected patients, especially those with CD4⁺ lymphocyte counts less than 150 cells/ μ L, should avoid activities that would potentially increase their exposure, including cleaning chicken coops, disturbing native soil beneath bird-roosting sites, cleaning, remodeling, or demolishing old buildings, and exploring caves.²⁹

Prevention of Disease. Routine serologic testing, even in histoplasmosis-endemic areas, is not recommended. Itraconazole for primary *H. capsulatum* prophylaxis can be considered in those who have a CD4⁺ lymphocyte count less than 150 cells/ μ L and who are at high-risk due to occupation or who live in hyperendemic regions.²⁹

Coccidioides immitis

Coccidioidomycosis is caused by the dimorphic, soil-dwelling fungi *C. immitis* and *Coccidioides posadasii*. As described in Chapter 37, the chief manifestation of coccidioidomycosis is as a mild flulike, often undiagnosed illness, from which most previously healthy people spontaneously recover. Chronic pulmonary disease manifests in roughly 5% of infected persons and disseminated disease in even fewer. Manifestations of coccidioidomycosis in HIV-infected persons include focal or diffuse pneumonia, cutaneous disease, meningitis, liver or lymph node involvement, or disseminated disease that can be fatal. The fungus is endemic to the semiarid regions of North America, notably the southwestern United States (central California, southern Arizona, southern New Mexico, and west Texas) and also northern Mexico.^{184,218} California's southern San Joaquin Valley and southern Arizona are hyperendemic areas.²¹⁸ *Coccidioides* is also found in South America, especially central Argentina. In soil, the fungus exists in a mycelial form with characteristic arthrospores. When the soil is disrupted, the few micrometer-diameter arthrospores, which are just the right size for deposition in the distal airways and alveoli after inhalation, become airborne. After deposition in the lungs, the arthrospores transform into spherules that may develop several hundred endospores. Rupture of the spherules allows widespread dissemination of the endospores, which then form additional spherules, replicating the cycle. Although most cases of HIV-associated coccidioidomycosis appear to result from de novo inhalation, disease may also reactivate.

Clinical Features. The clinical presentation is often nonspecific; fever and chills (68%), night sweats (36%), and weight loss (50%) are all common.²¹⁹ Although the portal of entry is the lung, coccidioidomycosis can present with disseminated disease and meningitis. Other frequently involved sites include the skin, lymph nodes, liver, and skeletal system. In one study, 42% of HIV-infected patients with coccidioidomycosis presented with disseminated disease; overall, 25% of the patients in this series died.²²⁰ Focal

pneumonia can present similarly to bacterial pneumonia, and diffuse pulmonary involvement can be difficult to distinguish from PCP.

CD4⁺ Lymphocyte Count. Most cases of disseminated coccidioidomycosis are seen in patients with a CD4⁺ lymphocyte count less than 100 cells/ μ L and often fewer than 50 cells/ μ L.^{219,220} Focal pneumonia is more common when the CD4⁺ cell count is greater than 250 cells/ μ L.²⁹ Cerebrospinal fluid examination is warranted in all patients with suspected disseminated coccidioidomycosis.

Imaging. In a series of 91 HIV-infected patients with coccidioidomycosis, diffuse reticulonodular opacities (see Fig. 37-5) were seen in 65%; focal opacities were less common, in 14% of cases, and consisted of focal opacities, single or multiple nodules, and cavities.²¹⁹ A miliary pattern may be seen (eFig. 90-26). Pleural effusion and hilar adenopathy as well as normal chest radiographs have all been reported.

Diagnosis. Serologic tests are useful in the evaluation of suspected coccidioidomycosis. Several studies have found an 80% to 90% sensitivity of complement fixation and tube precipitin tests.²²¹ Sensitivity of enzyme-linked immunoassays may be higher, but may be less specific. False-negative titers usually arise in the most severely immunocompromised patients with diffuse pulmonary disease; in those with positive tests, the titer appeared to reflect the disease activity and proved useful for monitoring response to therapy.²²² A urinary and serum antigen test specific to coccidioides has been developed and is useful for diagnosis of severe cases of coccidioidomycosis; however, other endemic fungi, including *Histoplasma* or *Blastomyces*, can cross-react.^{223,224}

A definitive diagnosis can be established by isolation and identification of the fungus by culture or identification of pathognomonic giant spherules in cytologic or histologic preparations. In cases of suspected coccidioidomycosis, it is critical to alert the microbiology laboratory so that proper precautions can be implemented to prevent laboratory transmission. Direct examination and culture of sputum, BAL fluid, or TBB can establish the diagnosis of pulmonary coccidioidomycosis in HIV-infected patients. Singh and associates²¹⁹ found that sputum culture in 13 of 19 cases (68%) and cytology in 8 of 11 cases (73%) had a high yield. BAL fluid culture diagnosed 29 of 42 cases (69%), and BAL fluid cytology diagnosed 32 of 48 cases (67%); in addition, TBB culture diagnosed 8 of 10 cases (80%), and biopsy histology diagnosed all 14 cases (100%).

Treatment. Either amphotericin B or a lipid formulation of amphotericin B is the treatment of choice for HIV-infected patients with severe (i.e., diffuse) pulmonary or disseminated coccidioidomycosis.²⁹ Treatment with amphotericin B should be continued until the patient is clinically improved, at which point the patient can be switched to fluconazole or itraconazole. Monitoring complement-fixing antibody titers every 12 weeks can be useful to assess response to therapy.²⁹ In patients with clinically mild infection, such as focal pneumonia, fluconazole or itraconazole may be used throughout.²⁹ Although clinical experience is limited,

voriconazole or posaconazole may be considered in refractory coccidioidomycosis.²²⁵ In patients with severe, diffuse disease, lifelong suppressive therapy with fluconazole or itraconazole should be continued after initial treatment is complete, particularly in those with meningeal involvement because the risk of relapse is high.²⁹ In patients who have had focal coccidioid pneumonia, and who have had a sustained response to ART with CD4⁺ lymphocyte counts greater than 250 cells/ μ L, therapy may be discontinued after 12 months, but periodic surveillance with chest radiograph and coccidioides serology is recommended.²⁹

Prevention of Exposure. In areas endemic for *C. immitis*, HIV-infected persons should avoid activities that will potentially increase their exposure, such as visits to construction or other sites where soil is being disturbed.

Prevention of Disease. Routine serologic testing is reasonable only in endemic areas. Pre-emptive treatment for persons living in or who have traveled to an endemic area is recommended only if the serology test result is newly positive and CD4⁺ lymphocyte count is less than 250 cells/ μ L.²⁹

Aspergillus Species

Species of *Aspergillus* are found worldwide, and exposure is universal. Nevertheless, disease is infrequent unless phagocyte number or function is reduced.²²⁶ Presently, greater than 180 species within the *Aspergillus* genus have been identified. *Aspergillus fumigatus*, however, is the most common disease-causing species, and it accounts for approximately 90% of cases of invasive aspergillosis. Although invasive aspergillosis is a well-documented complication of various immunosuppressive disorders, particularly in patients with hematologic malignancy or organ transplantation, it is an uncommon problem in patients with HIV disease. Risk factors for the development of aspergillosis other than HIV-induced immunosuppression included use of corticosteroids, neutropenia, marijuana use, and broad-spectrum antimicrobial drugs.²²⁷ In the ART era, the incidence of invasive aspergillosis has further declined. Holding and coworkers²²⁸ reported an aspergillosis incidence of 3.5 cases per 1000 person-years among HIV-infected individuals enrolled in the CDC-led Adult and Adolescent Spectrum of HIV Disease study.

Clinical Features. The entire spectrum of *Aspergillus*-related lung disease (Chapter 38) has been observed in HIV-infected persons, from colonization of the respiratory tract or a preexisting cavity, to tracheobronchitis or obstructing bronchial aspergillosis, to invasive aspergillosis, by far the most severe manifestation.^{227,229-231} Although most patients with invasive aspergillosis have a CD4⁺ lymphocyte count lower than 100 cells/ μ L, the classic risk factors for the disease relate more to phagocyte number and function (as determined by neutropenia and/or monocytopenia and use of corticosteroids or broad-spectrum antibiotics) than to absolute CD4⁺ lymphocyte counts. Patients with aspergillosis typically present with fever, cough, dyspnea, and occasionally pleuritic chest pain. Hemoptysis is another presenting feature. The imaging findings are variable and include unilateral or bilateral opacities, cavitary lesions

(eFigs. 90-27 and 90-28), nodular (see eFig. 90-28) and pleural-based opacities, and pleural effusions.²³²

Diagnosis. The definitive diagnosis of aspergillosis requires both demonstration of tissue invasion and isolation of the organism by culture. Neither sputum nor BAL is sufficient. Microscopy alone cannot distinguish *Aspergillus* species from *Fusarium* or *Pseudallescheria* species. The results of TBB are usually negative, but specimens from sputum, BAL fluid, or percutaneous aspirates are often positive on culture. The absence of histologic proof of tissue invasion is always somewhat disquieting, especially in attempting to distinguish invasive disease from possible colonization of damaged airways. Repeated isolation of the fungus in large numbers with a compatible clinical setting makes the diagnosis more tenable.

Galactomannan antigen testing on serum or BAL specimens is useful in the diagnosis of invasive pulmonary aspergillosis in other immunocompromised patients (see also Chapters 17 and 38),²³³ although its performance has not been prospectively evaluated in HIV-infected patients with suspected aspergillosis. Several other fungi, including *Histoplasma* and *Blastomyces*, can cross-react.²³⁴

Treatment. Compared with the fungi previously discussed, there is relatively little experience treating aspergillosis in HIV-infected patients.²²⁶ Voriconazole is the first-line recommended therapy.²⁹ Alternative agents include amphotericin, caspofungin, and posaconazole. Interactions with ART drugs must be considered because the antifungal azoles inhibit the cytochrome P450 system. Even with the prompt institution of therapy, the prognosis is poor, largely because aspergillosis is nearly always a late complication of advanced HIV disease.

Prevention of Exposure. Given the ubiquitous nature of *Aspergillus* species, it is impossible to prevent exposure to the organism. However, patients with advanced HIV disease should avoid activities that will potentially increase their exposure, including being near decaying vegetation (e.g., compost) and soil.

Prevention of Disease. There are no specific recommendations regarding chemoprophylaxis for *Aspergillus* species.²⁹

Blastomyces dermatitidis

Blastomycosis is a disease caused by the endemic, dimorphic fungus *Blastomyces dermatitidis*. Blastomycosis is co-endemic with histoplasmosis throughout much of the central United States (Chapter 37), but it is less common than histoplasmosis, and reports of HIV-associated blastomycosis are infrequent.^{235,236}

Clinical Features. The largest case series reported 15 cases of HIV-associated blastomycosis; all but one patient had a CD4⁺ lymphocyte count less than 200 cells/ μ L.²³⁵ The authors noted two distinct patterns of disease: one group of patients had disease that was clinically limited to the respiratory system, whereas the other group had disseminated blastomycosis, commonly involving multiple organ systems, including the lungs. Eleven of 15 patients (73%) had abnormal chest radiographs, with diffuse interstitial or miliary

disease (55%) as the most common radiographic finding. Definitive diagnosis requires the growth of *B. dermatitidis*, although visualization of the characteristic budding yeast form is strongly suggestive and therefore warrants antifungal therapy while awaiting the results of culture.

Treatment. Intravenous amphotericin B is the treatment of choice for HIV-infected patients with severe disease.^{235,236} Treatment with amphotericin B should be continued until there is clinical improvement; patients can then be switched to oral itraconazole maintenance therapy for at least 12 months, with itraconazole continued indefinitely for AIDS patients without immune reconstitution.²³⁷ With prompt institution of therapy, most patients with disease limited to the lungs respond well; in contrast, patients with disseminated disease do poorly (40% mortality in 30 days).²³⁵

Penicillium marneffei

Penicilliosis is a disease caused by *P. marneffei*, a dimorphic, soil-dwelling fungus. *P. marneffei* is endemic in southeastern Asian countries, and, in northern Thailand, it is the third most common opportunistic infection (after tuberculosis and cryptococcosis) in HIV-infected patients with AIDS, accounting for 15% to 20% of all AIDS-related illnesses.^{238,239} Disease is related to soil exposure, especially during the rainy season (May to October), and infection is probably acquired via inhalation.

Clinical Features. Most cases of penicilliosis are seen in patients with a CD4⁺ lymphocyte count less than 100 cells/ μ L. The clinical presentation is often mistaken for tuberculosis, cryptococcosis, or histoplasmosis. The most common symptoms include fever, weight loss, cough, and generalized papular skin lesions, usually with central umbilication.²⁴⁰ Symptoms are often present for weeks. In addition to the cutaneous findings, physical examination often reveals peripheral lymphadenopathy and hepatomegaly. Anemia is a prominent laboratory finding.

Diagnosis. *P. marneffei* is most commonly a disseminated disease in HIV-infected patients, and the diagnosis is usually made by fungal blood cultures. Other involved sites include the skin, lymph nodes, bone marrow, and lungs. In contrast to other *Penicillium* species that cause disease in humans, *P. marneffei* converts to a yeast form in its host, and yeast-laden macrophages can often be seen in peripheral blood, bone marrow aspirates, and touch preparations from tissue biopsies.

Treatment. Amphotericin B, followed by itraconazole, is the standard treatment for *P. marneffei*.²⁹ Mild forms of disease can be treated initially with itraconazole. The duration of amphotericin B treatment is 2 weeks, followed by an additional 10 weeks of itraconazole. This regimen is reported to have a greater than 97% response rate for disseminated *P. marneffei* infection.²⁴¹ Voriconazole is an alternative drug for primary treatment.²⁹ Without secondary prophylaxis, most patients will suffer a relapse within 6 to 12 months. Secondary prophylaxis can be discontinued in patients who are started on ART and have a sustained CD4⁺ lymphocyte count more than 100 cells/ μ L for more than 6 months.²⁹

Prevention of Exposure. Given the strong association with soil exposure, especially during the rainy season, HIV-infected patients living in endemic areas should avoid activities that will potentially increase their exposure. Current CDC, NIH, and HIVMA/IDSA guidelines suggest that HIV-infected patients avoid visiting endemic areas if possible.²⁹

Prevention of Disease. Itraconazole is recommended as primary prophylaxis against *P. marneffei* for subjects in endemic areas who have CD4⁺ cell counts less than 100 cells/ μ L.^{29,242} Fluconazole is a second-line alternative.

Candida Species

Despite the high frequency of mucocutaneous candidiasis in HIV-infected patients, pulmonary candidiasis is distinctly uncommon and is rarely diagnosed during life.²⁴³ Because of the small number of documented cases of pulmonary candidiasis, neither the clinical features nor the treatment is well established. Tissue invasion must be demonstrated by biopsy for a convincing diagnosis; the mere identification of the fungus in respiratory secretions by culture alone is insufficient.

VIRUSES

Many viruses are known to cause pulmonary disease in immunosuppressed persons; however, only CMV is regarded as a potentially important agent of pulmonary disease in HIV-infected persons.

Cytomegalovirus

CMV, a double-stranded DNA virus in the Herpesvirus family, is described in Chapter 32. The risk of exposure to CMV increases with age, and evidence of CMV infection is extremely common in healthy persons. In HIV-infected patients, CMV disease is believed to result chiefly from reactivation of latent infection; however, disease has been documented from de novo infection in recipients of solid organs, bone marrow, and blood, which raises the possibility that new infection or superinfection from exogenous sources may also arise in HIV-infected persons. Although clearly the source of significant pathologic conditions in the retina, gastrointestinal tract, and nervous system, the role of CMV in producing pulmonary disease in HIV-infected persons is open to question. Many consider this ubiquitous virus a “passenger” rather than a pathogen in most instances. However, there are also clear instances in which documented pulmonary disease results from CMV.

Clinical Features. Retinitis and gastrointestinal disease are the two most common forms of HIV-associated CMV disease. CMV is a frequent isolate from the BAL fluid of patients with advanced immunosuppression who undergo evaluation for opportunistic infections, notably *Pneumocystis*. Because CMV is shed in respiratory secretions, its mere presence in BAL fluid cannot be construed as diagnostic of CMV pulmonary disease. When dual pulmonary infection is discovered, treatment directed against the coexisting disease and not against CMV usually results in clinical resolution²⁴⁴; however, sometimes CMV causes pulmonary disease, and the challenge for clinicians is to recognize these instances.^{245,246}

The most common symptoms of CMV pneumonia are cough, dyspnea, and fever. In a study by Salomon and associates,²⁴⁶ these symptoms were seen in 94%, 94%, and 89%, respectively, of the 18 patients reported. Respiratory symptoms were present for up to 2 weeks in 50% and between 2 and 4 weeks in an additional 44%.

CD4⁺ Lymphocyte Count. Most cases of CMV disease are seen in patients with a CD4⁺ lymphocyte count less than 50 cells/ μ L. In one study of 18 patients with biopsy-proven CMV pneumonia, the median CD4⁺ lymphocyte count was 4 cells/ μ L.²⁴⁶ The serum LDH has been reported to be elevated in CMV pneumonia.²⁴⁶

Imaging. The imaging findings of CMV pneumonia vary and include reticular or ground-glass, alveolar, and nodular opacities (eFig. 90-29).²⁴⁶ Pleural effusions may be seen as well.

Diagnosis. When CMV pulmonary disease is suspected in conjunction with other end-organ disease (e.g., retinitis), CMV therapy must be initiated immediately. CMV is usually a disseminated disease and commonly involves multiple organ systems simultaneously. Treatment of CMV disease in one end-organ treats all affected organs, although the length of therapy can differ by organ system. The therapeutic dilemma is much greater when only the lungs appear to be afflicted. The only precise criterion for diagnosis of CMV pulmonary disease is the demonstration of widespread specific cytopathic changes in the lungs. Neither culture of BAL fluid²⁴⁷ nor cytopathic inclusions on TBB specimens are sufficient to make the diagnosis of CMV pneumonitis. Patients suspected of having CMV pneumonitis should undergo a careful dilated retinal examination performed by an experienced ophthalmologist, even if there are no ocular complaints.

Treatment. Data for treatment of CMV pneumonia in HIV-infected patients are limited. Intravenous ganciclovir or foscarnet is recommended for severe pneumonitis.²⁹ Although oral valganciclovir has been suggested for less severe pneumonitis, there are no data regarding its use in this setting.²⁹ With these drugs, an initial course of induction therapy should be continued until there is clinical improvement; the length of induction therapy for CMV pneumonia, however, is undetermined. A 21-day course for isolated CMV pneumonitis has been recommended. The usefulness of maintenance therapy in preventing a relapse of CMV pneumonitis is unclear.

Prevention of Exposure. HIV-infected patients who are CMV immunoglobulin G negative should be given CMV-negative blood in the event that a transfusion is necessary.

Prevention of Disease. CMV disease is best prevented by maintaining CD4⁺ lymphocyte counts greater than 100 cells/ μ L with ART.²⁹

Other Viruses

Symptomatic pulmonary viral infection other than CMV is uncommon. Herpes simplex virus, while frequently cultured from BAL fluid, is usually a contaminant from upper

airway carriage. Lower respiratory tract involvement is rare in HIV-infected persons (0.2% to 4% of autopsy cases) and appears to be more frequent in other immunosuppressed hosts. Herpes simplex virus pulmonary disease causes a focal pneumonia or a diffuse interstitial pneumonitis.²⁴⁸ The focal pneumonias appear to result from contiguous spread of herpes simplex virus to the lung parenchyma and are often associated with necrotizing tracheobronchitis, whereas the diffuse interstitial pneumonias appear to be a manifestation of hematogenous herpes simplex virus dissemination. Varicella-zoster virus is a rare cause of pneumonia in HIV-infected adult patients.²⁴⁹ Epstein-Barr virus DNA has been identified in lung biopsy specimens of infants and children with lymphocytic interstitial pneumonitis, but the precise role of the virus in this disease is uncertain.²⁵⁰

Influenza-related mortality is increased in adults with AIDS compared to the general population in studies using data from the United States as well as from sub-Saharan Africa.^{251,252} Influenza-related mortality is decreased in the ART era, but remains greater in those with AIDS compared to the general U.S. population. Influenza generally presents similarly and has a comparable clinical course in HIV-infected as in non-HIV-infected adults. Studies focused on H1N1 influenza generally confirmed these findings, although HIV-infected patients with more advanced HIV disease had a poorer prognosis than those with well-controlled HIV.²⁵³⁻²⁵⁸ Prompt initiation of antiviral therapy directed against influenza in HIV-infected patients with suspected or confirmed disease is recommended. All HIV-infected persons should receive the inactivated influenza vaccine annually.²⁹

PARASITES

Of the classic unicellular and multicellular parasites that afflict otherwise healthy humans (Chapter 39), several also cause pulmonary disease in HIV-infected hosts. Of these, *T. gondii* is the most frequent.

Toxoplasma gondii

Toxoplasmosis is a zoonosis caused by the intracellular protozoan *T. gondii*, with domestic cats as its definitive host, but with an infectious reservoir that encompasses all animals. Infection is transmitted to humans when raw or undercooked meat containing *T. gondii* is eaten. Domestic cat feces in litter boxes are an additional source of potential *T. gondii* infection. Infection can be transmitted vertically from mother to fetus. In HIV-infected patients, the majority of cases of toxoplasmosis result from reactivation of chronic, latent infection. Thus, the keys to preventing toxoplasmosis are prevention of exposure for those not yet infected and prophylaxis for those already seropositive. The seroprevalence of *Toxoplasma* antibodies varies. In the United States, the seroprevalence is 10% to 50%, whereas in Western Europe, the seroprevalence may be as high as 90%.

Clinical Features. Central nervous system complications of *T. gondii* are well recognized in HIV disease and include encephalitis as well as focal brain abscess. Pulmonary involvement is uncommon, but is seen in patients with central nervous system or disseminated disease, can present

as isolated pneumonia, and can rarely be associated with acute respiratory distress syndrome.²⁵⁹⁻²⁶¹

CD4⁺ Lymphocyte Count. Toxoplasmosis presents at the lower range of CD4⁺ lymphocyte counts. In a large study of 64 patients with pulmonary toxoplasmosis conducted in France, the mean (\pm standard deviation [SD]) CD4⁺ lymphocyte count was 40 (\pm 75) cells/ μ L.²⁶⁰

Imaging. The chest radiograph usually reveals bilateral opacities, either in a fine reticulonodular pattern indistinguishable from PCP or in a coarse nodular pattern similar to that seen with tuberculosis or fungal pneumonias.²⁶² Pleural effusions can be seen, and a variety of other radiographic findings have also been described.²⁶³

Diagnosis. The diagnosis of pulmonary toxoplasmosis is usually established by bronchoscopy and study of BAL fluid. In one review, BAL fluid examination was diagnostic in 16 of 17 immunocompromised patients with pulmonary disease.²⁶³

Treatment. The treatment for pulmonary toxoplasmosis is identical to that for central nervous system toxoplasmosis. First-line treatment is sulfadiazine plus pyrimethamine with leucovorin to decrease the likelihood of hematologic toxicities associated with pyrimethamine.²⁹ The preferred alternative regimen is clindamycin plus pyrimethamine with leucovorin.²⁹

Prevention of Exposure. Persons who are *Toxoplasma* antibody negative should be instructed to avoid potential sources of infection.

Prevention of Disease. HIV-infected persons should be tested for *T. gondii* antibodies; antibody seronegative patients should be re-tested if their CD4⁺ lymphocyte count falls below 100 cells/ μ L. Toxoplasma seropositive patients receive primary prophylaxis once their CD4⁺ lymphocyte count falls below 100 cells/ μ L.²⁹ As a practical matter, this is often accomplished when the CD4⁺ lymphocyte count reaches 200 cells/ μ L or fewer because the prophylaxis of choice (TMP-SMX) is also the prophylaxis of choice for *Pneumocystis*. For patients who are intolerant of TMP-SMX, dapsone plus pyrimethamine/leucovorin or atovaquone with or without pyrimethamine/leucovorin can also be used.²⁹ Primary and secondary *T. gondii* prophylaxis can be discontinued in HIV-infected persons on ART who have experienced an increase in their CD4⁺ lymphocyte count to greater than 200 cells/ μ L for at least 3 to 6 months.²⁹

Other Parasites

In general, pulmonary helminth infections are uncommon in HIV-infected persons.^{264,265} Both pulmonary cryptosporidiosis and pulmonary microsporidiosis in HIV-infected patients with concurrent intestinal disease have been reported.²⁶⁶ In these cases, aspiration from the gastrointestinal tract appears to be the most probable route of pulmonary infection. Occasionally, patients have presented with disseminated disease, raising the likely possibility of hematogenous spread. The most common respiratory symptoms are cough, dyspnea, and pleuritic chest pain. One review

found that these symptoms were present in 77%, 58%, and 33%, respectively, of patients with cryptosporidial pulmonary disease.²⁶⁶ The diagnosis of *Strongyloides stercoralis* pulmonary disease (eFig. 90-30) can be made by either sputum study or bronchoscopy.^{267,268} *Strongyloides* hyperinfection syndrome has also been reported in HIV-infected patients,²⁶⁹ but does not appear to be an important HIV-associated complication, even in countries where the parasite is endemic.²⁷⁰

NONINFECTIOUS DISORDERS

The evaluation of respiratory complications usually focuses on the diagnosis of HIV-associated opportunistic infections because of their frequency, the need for prompt therapy, and, in the case of tuberculosis, the concern for transmission to other persons, both HIV-infected and non-HIV infected. As more people are living with HIV/AIDS and are living longer on effective ART, noninfectious complications and comorbid illnesses among these HIV-positive patients have increased in frequency.²⁷¹ In addition to an increased risk for infectious diseases, HIV-infected patients appear to have an increased risk for a number of noninfectious pulmonary diseases, including COPD, lung cancer, and PAH.²⁷² Increasing age and a high prevalence of cigarette smoking combined with an independent risk from HIV infection itself may all contribute, particularly to the increases in COPD and lung cancer.^{273,274} Noninfectious pulmonary diseases that may be encountered in HIV are reviewed here.

MALIGNANCIES

Two different HIV-associated malignancies, KS and NHL, may involve the thorax, including the lung parenchyma, airways, pleura, or hilar or mediastinal lymph nodes. Intrathoracic disease from either neoplasm is usually a manifestation of disease already recognized elsewhere, but occasionally both KS and NHL may present with isolated pulmonary disease.²⁷⁵

Kaposi Sarcoma

The most common HIV-associated malignancy is KS, although its incidence has decreased dramatically with ART.²⁷⁶⁻²⁷⁸ KS is an angioproliferative tumor that is associated with *human herpesvirus 8* (HHV8; also termed the KS-associated herpesvirus).²⁷⁹⁻²⁸¹ KS most commonly presents with mucocutaneous involvement. The lymph nodes, gastrointestinal tract, and lungs can also be involved. Approximately 90% to 95% of cases of KS are seen in MSM.²⁸²

Clinical Features. Pulmonary KS is detected clinically in approximately one third of patients with known KS, with the proportion detected at autopsy approaching 50% to 75%. Most but not all patients with pulmonary KS have concomitant mucocutaneous disease. Huang and coworkers²⁸³ found that 85% of 168 consecutive patients diagnosed with pulmonary KS by bronchoscopy had evidence of mucocutaneous involvement at the time of bronchoscopy. The 15% without mucocutaneous involvement had pulmonary disease that ranged from isolated tracheal

lesions to diffuse endobronchial involvement that was ultimately fatal. A significant proportion of patients with pulmonary KS also have a concurrent opportunistic infection. For example, in the study by Huang and coworkers,²⁸³ 45 of the 168 patients (27%) with pulmonary KS had accompanying opportunistic infection, most frequently PCP. These observations underscore the need to evaluate each patient with KS who presents with respiratory symptoms not only for pulmonary KS, but also for opportunistic infection. Patients with pulmonary KS who develop opportunistic infection may also experience a rapid progression of their KS that mimics an infectious process.

CD4⁺ Lymphocyte Count. Pulmonary KS presents at the lower range of CD4⁺ lymphocyte counts. In one study of 168 patients with pulmonary involvement from KS, the median CD4⁺ lymphocyte count was 19 cells/ μ L; 68% had a CD4⁺ lymphocyte count less than 50 cells/ μ L, and only 4% had a CD4⁺ lymphocyte count greater than 200 cells/ μ L.²⁸³ Patients with KS pulmonary involvement appear to have lower CD4⁺ lymphocyte counts than those without pulmonary involvement.

Imaging. Pulmonary KS characteristically presents with bilateral opacities in a central or perihilar distribution, as shown in Figure 90-8 and eFig. 90-31A. Typical findings include linear opacities, nodules or nodular opacities of varying size, pleural effusions, and intrathoracic adenopathy. Gruden and associates²⁸⁴ reviewed the chest radiographic presentation of 76 consecutive patients with pulmonary KS diagnosed by bronchoscopy whose BAL was negative for infectious organisms. In this study, 95% of the radiographs had peribronchial cuffing and “tram track” opacities, with or without more extensive perihilar coalescent opacities (see eFig. 90-31A). Small nodules or nodular opacities were seen in 78%, Kerley B lines in 71%, and pleural effusions in 53% of the radiographs. Although these

Figure 90-8 Kaposi sarcoma. Frontal chest radiograph of an HIV-infected patient with pulmonary Kaposi sarcoma diagnosed by bronchoscopy showing the characteristic bilateral, perihilar distribution of abnormalities consisting of nodules and nodular opacities. (Courtesy L. Huang.)

Figure 90-9 Kaposi sarcoma. Characteristic Kaposi sarcoma lesions in the trachea of an HIV-seropositive patient seen via bronchoscopy. (Courtesy L. Huang.)

radiographic findings strongly suggest the diagnosis of pulmonary KS in HIV-infected MSM, no radiograph is diagnostic for KS. Therefore, patients with suspected pulmonary KS should have their diagnosis confirmed. Chest CT findings in patients with pulmonary KS (see eFig. 90-31B-D) include “flame-shaped” areas of peribronchovascular ground-glass opacity and nodularity, often with interlobular septal thickening and pleural effusion, and, less commonly, lymphadenopathy. Atypical imaging manifestations of KS are occasionally encountered (eFig. 90-32).

Diagnosis. The diagnosis of pulmonary KS is usually established by bronchoscopy. The observation of characteristic endobronchial, red or violaceous, flat or slightly raised lesions is sufficient to diagnose pulmonary involvement (Fig. 90-9). The presence of these mucosal lesions does not preclude a concurrent infection, nor does their absence in the observable airway preclude more distal disease or parenchymal, pleural, or nodal involvement. Although endobronchial or transbronchial biopsy of the airway or parenchymal abnormalities, respectively, is usually unnecessary, we have occasionally established the diagnosis by TBB in patients in whom there was a strong clinical and radiographic suspicion for pulmonary KS, but who had no visible endobronchial lesions. HHV8 may be detected in BAL. Patients with cutaneous KS who develop new respiratory complaints should undergo a thorough evaluation to rule out an opportunistic infection or other process; however, patients in whom there is a strong clinical suspicion for pulmonary KS should undergo bronchoscopy as the initial procedure. Cytologic evaluation of pleural fluid and thoracoscopic biopsy of the pleura in patients with KS are not typically useful for diagnosis.²⁸⁵

KS is negative on gallium scans. In contrast, opportunistic infections and NHL are gallium avid. Among HIV-

associated pulmonary diseases, this unique feature of KS has created a clinical niche for the use of gallium scans. In the absence of either a bronchoscopic or tissue diagnosis of pulmonary KS, its presence may be inferred by the finding of significant chest radiographic abnormalities and a negative gallium scan.

Treatment. Tumors can regress in size and number in response to ART, and therefore all patients with KS should receive ART if no contraindications exist.²⁸⁶ Treatment of more advanced systemic disease also includes chemotherapy, with doxorubicin or daunorubicin generally recommended as first-line agents. Mortality in patients with KS may be related to an increased rate of other malignancies, particularly lymphomas.²⁸⁷ Survival in patients with pulmonary KS appears substantially worse when compared with that in patients without pulmonary involvement: 5-year overall survival was reported to be 49% in patients with pulmonary KS compared with 82% in patients without pulmonary involvement ($P < 0.0001$).²⁸⁸ Of malignancies, KS is the most likely to be associated with IRIS in patients who initiate ART. KS-associated IRIS may manifest with worsening of underlying pulmonary lesions,²⁸⁹ and can result in death, particularly in patients with visceral KS.²⁹⁰

Non-Hodgkin Lymphoma

Almost all HIV-associated NHLs are of B-cell origin. Most are classified as small, noncleaved Burkitt, diffuse large cell with centroblastic features, or diffuse large cell with immunoblastic features.²⁹¹ The majority are associated with Epstein-Barr virus infection. Many HIV-infected patients have an advanced stage of disease at the time of presentation. As with KS, the incidence of NHL has declined dramatically in the era of ART.²⁷⁸

Clinical Features. Most HIV-infected patients with NHL present with disseminated disease and extranodal involvement.²⁹² Frequent extranodal sites include the liver, spleen, bone marrow, meninges, gastrointestinal tract, and pericardium. Intrathoracic involvement is seen in a smaller proportion. The reported incidence of intrathoracic disease ranges up to 31% of patients at the time of clinical diagnosis and is usually higher at the time of autopsy. Occasionally, the lung is the only site involved.

CD4⁺ Lymphocyte Count. NHL can present at a wide range of CD4⁺ lymphocyte counts, although typically patients are more severely immunocompromised. The median CD4⁺ T-lymphocyte count is approximately 100 cells/ μ L, and 75% of patients have a CD4⁺ lymphocyte count greater than 50 cells/ μ L. In one study of 38 patients with NHL, the mean (\pm SD) CD4⁺ lymphocyte count was 67 (\pm 65) cells/ μ L.²⁹³

Imaging. The most common chest radiograph parenchymal findings include single (Fig. 90-10; eFig. 90-33) or multiple nodules (eFig. 90-34), nodular opacities or masses (eFig. 90-35), lobar opacities, and diffuse interstitial opacities (eFig. 90-36).²⁹³ More rarely, cases of endobronchial lesions have been reported.²⁹⁴ Pleural effusions are the most common radiographic abnormality, seen in 40% to 70% of cases, and are often bilateral.²⁹³ Bilateral hilar and

Figure 90-10 Non-Hodgkin lymphoma. **A**, Frontal chest radiograph from an AIDS patient with non-Hodgkin lymphoma showing a large left lower lobe mass. **B**, Axial CT shows a mass in the left lower lobe without an air bronchogram, suggestive of a neoplasm. (Courtesy Michael B. Gotway, MD.)

mediastinal adenopathy can be found in up to 60% of patients. Isolated intrathoracic adenopathy without identifiable extrathoracic nodal involvement is a rare presentation for HIV-associated NHL.

Diagnosis. The diagnosis of NHL requires demonstration of malignant lymphocytes on cytology or biopsy specimens. Most often the diagnosis is made by needle aspiration or biopsy of an extrathoracic site. Persons who present with isolated intrathoracic involvement should undergo bronchoscopy with TBB and needle biopsy, if abnormal nodes are within reach through the bronchoscope.²⁹³ For lesions outside the sampling distance of the bronchoscope, fluoroscopic or CT-guided fine-needle aspiration should be considered. Other options include mediastinoscopy and open-lung biopsy. For patients with pleural effusions, pleural fluid cytology, biopsy, or both are often diagnostic.²⁹³ Pleural fluid is exudative, lymphocytic predominant, and often has very high levels of LDH.²⁹³ The yield of pleural cytology is significantly higher in HIV-associated pulmonary lymphoma than in non-HIV-infected cases.²⁹⁵

Treatment. Pulmonary involvement in NHL is treated as part of systemic disease. Median survival from AIDS-related NHL has greatly improved as a result of combining ART with chemotherapy.²⁹⁶ Chemotherapy is frequently complicated by the development of opportunistic infections, particularly PCP, and by the presence of decreased bone marrow reserve. Therefore, *Pneumocystis* prophylaxis should be considered in all cases, regardless of CD4⁺ lymphocyte count.

Primary Effusion Lymphoma

Classic primary effusion lymphoma is a distinct subtype of NHL that presents with isolated effusions in body cavities, including the pleura (eFig. 90-37), pericardium, and peritoneum.²⁹⁷ Primary effusion lymphoma typically presents with lymphomatous effusions in the absence of a discrete nodal or extranodal mass. A rare disease, these tumors are found nearly exclusively in HIV-infected MSM. HIV infection is usually advanced; in one study peripheral CD4⁺ lymphocyte counts averaged 200 cells/ μ L.²⁹⁷ HIV-infected patients with primary pleural effusion lymphoma typically present with symptoms related to the space-occupying nature of the effusion (i.e., dyspnea). Diagnosis is estab-

lished by pleural fluid histology and identification of HHV8, which can be found in all cases.²⁹⁸ Primary effusion lymphomas are of a null phenotype, lacking classic B-cell and T-cell markers.²⁸⁶ Prognosis is poor, with median survival of approximately 6 months. Treatment options include ART and systemic chemotherapy. Chemotherapy agents known to have activity against intermediate- and high-grade NHL may be used. Prolonged survival has been reported in patients treated with cidofovir or ganciclovir as adjunctive antiviral therapy.²⁸⁶

Multicentric Castleman Disease

Multicentric Castleman disease (MCD) is a rare lymphoproliferative disorder of the plasma cell type.²⁹⁹ It is characterized histologically as angiofollicular lymph node hyperplasia.²⁸⁵ MCD may be associated with KS in HIV-infected as well as in non-HIV-infected patients. Most HIV-infected patients with MCD are also infected with HHV8. MCD can be seen in patients with controlled or uncontrolled HIV. Common presenting symptoms and signs of systemic MCD can mimic lymphoma and include fever, weakness, generalized lymphadenopathy (eFig. 90-38), anemia, and hypergammaglobulinemia as well as hemophagocytic syndrome in life-threatening forms of MCD.²⁸⁵ MCD can present with nonspecific respiratory symptoms such as cough and dyspnea in 33% to 75% of cases.²⁸⁵ Bilateral crackles may be present on physical examination. Chest radiographic findings include reticular and/or nodular interstitial patterns, with mediastinal lymphadenopathy and less commonly, bilateral pleural effusions.^{285,300} In another study, bronchovascular nodularity, consolidation, and mediastinal lymphadenopathy were described on chest CT.³⁰¹ PCR-assessed HHV8 viral load is usually increased; if a BAL is obtained, HHV8 may be detected, although bronchoscopy is not usually necessary for diagnosis of MCD.²⁸⁵ Instead, the diagnosis is typically based on pathologic evaluation of an involved lymph node or extranodal mass to confirm MCD, and to rule out other diseases such as tuberculosis or lymphoma. Involved cells are B cells with plasma-cell differentiation. HHV8-infected cells can be detected by immunohistochemistry. Prognosis is generally poor, and disease can recur. Treatment options are based on expert opinion and include initiation of ART, if the patient is not already on it, and anti-HHV8 therapy such as with ganciclovir.²⁸⁵ Systemic chemotherapy as well as monoclonal antibodies

against CD20 (rituximab) and interleukin-6 receptor (atlizumab) may be considered; reports of sustained remission have been associated with rituximab therapy.²⁸⁶ Cases of IRIS, some of them fatal, have been reported in patients with MCD initiated on ART.

Non–Small Cell Lung Cancer

The incidence of non–small cell lung cancer, but not small cell lung cancer, is greater among HIV-infected persons than among non–HIV-infected persons (see also Chapter 52).²⁷⁵ Whether this increased incidence is due to HIV infection or to other potential confounders such as increased smoking among HIV-infected populations has been controversial. Studies that account for potential confounding factors include work by Kirk and colleagues,³⁰² who analyzed lung cancer deaths in the ART era and found that HIV infection was an independent risk factor for lung cancer, after controlling for smoking status as well as age and sex (hazard ratio of 3.6; 95% confidence interval [CI], 1.6 to 7.9). In a study by Engels and colleagues,³⁰³ HIV infection was also associated with lung cancer, after adjusting for estimates of smoking prevalence (standardized incidence ratio of 2.5; 95% CI, 1.6 to 3.5). In the largest study to date with 457 cases of lung cancer in HIV-infected and 614 in non–HIV-infected patients, Sigel and colleagues³⁰⁴ also found an independently increased risk for lung cancer associated with HIV infection after controlling for smoking status and other risk factors (incidence rate ratio of 1.7; 95% CI, 1.5 to 1.9). Whereas AIDS-defining cancers such as KS and NHL have decreased, non–AIDS-defining cancers in HIV-infected patients have increased, primarily among HIV-infected persons aged 50 years and older.^{278,305} In HIV-infected persons, lung cancer is now the most common infection-unrelated, non–AIDS-defining cancer and is a leading cause of mortality.^{278,305-310}

Clinical Features. HIV-infected patients develop lung cancer at slightly younger ages than do non–HIV-infected patients after controlling for demographic differences (50 vs. 54 years in one study).³¹¹ A number of reports have suggested that lung cancer has a more aggressive course in HIV-infected patients, although this remains unclear. Most HIV-infected patients in whom lung cancer develops are cigarette smokers. Although all pathologic types are seen, adenocarcinoma has been the most frequent pathologic type reported, similar to that seen in non–HIV-infected patients; squamous cell carcinoma is the second most frequently observed pathologic type.^{303,304} It has been suggested that HIV-infected patients may be more likely to have advanced-stage disease at presentation, but whether this is due to detection bias is uncertain, and age-matched data do not support this finding.³¹² Furthermore, the study by Sigel and colleagues did not find a difference in stage of presentation by HIV status where nearly 70% of all patients were diagnosed at stage III/IV.³⁰⁴ Although lung cancer can develop at any CD4⁺ lymphocyte count, immunodeficiency is postulated as a mechanism for the enhanced risk for lung cancer associated with HIV.^{307,313,314} Prior lung disease and infections, particularly bacterial pneumonia and tuberculosis, are also purported risk factors and may partially explain the risk for lung cancer.³¹⁵ There is no apparent relationship between HIV viral load and use of ART with

lung cancer risk.³⁰² The characteristic presentation and radiographic finding of bronchogenic carcinoma, as described in Chapter 53, are similar in HIV-infected and non–HIV-infected patients (eFig. 90-39).

Diagnosis and Treatment. Diagnosis and treatment of lung cancer in an HIV-infected patient is similar to that in a non–HIV-infected individual. HIV infection should be considered an important concurrent underlying medical problem, much the same as one would consider underlying cardiopulmonary disease. Overall, mortality in HIV-infected patients with lung cancer appears to be independent of HIV, and median survival in HIV-infected patients with lung cancer is similar to age-matched non–HIV-infected lung cancer patients.³¹² Whether lung cancer screening with annual low-dose CT will have a beneficial effect on mortality in HIV-infected smokers as it has in older, non–HIV-infected heavy smokers in the national Lung Cancer Screening Trial³¹⁶ is unclear.^{316a,b}

PULMONARY ARTERIAL HYPERTENSION

Studies have reported an increased frequency of PAH in the HIV-infected population, with a prevalence of approximately 0.5%.³¹⁷ There is some debate about whether this diagnosis has decreased in the era of ART, but it still seems to be overrepresented in HIV-infected individuals.³¹⁸ PAH may be underdiagnosed in this population because screening echocardiograms detect increased pulmonary artery pressures in as many as 35% to more than 50% of HIV-infected cohorts.³¹⁹⁻³²¹ Echocardiography may not accurately reflect right heart pressures obtained on catheterization.³²² HIV-infected individuals with elevated echocardiographic pulmonary artery pressures have more respiratory complaints and lower diffusing capacity for carbon monoxide.³²⁰ Possible causes of PAH in HIV include the direct effects of HIV proteins, opiate use, and inflammation.³²³⁻³²⁵

Clinical Features

HIV-infected patients are significantly younger, and the proportion with New York Heart Association functional class III or IV is significantly lower (50% vs. 75%, $P = 0.01$), than in non–HIV-infected individuals with idiopathic PAH, and 1-year survival is approximately 51% to 88% depending on the cohort.^{326,327} Intravenous drug use is commonly reported in HIV-infected patients with PAH, and patients may be more likely to have more advanced HIV disease.^{320,327,328} In a review of 131 cases of PAH in HIV-infected patients,³²⁹ presenting symptoms and radiographic, pulmonary function, electrocardiographic, echocardiographic, and pathologic findings were similar to those in non–HIV-related idiopathic PAH (Chapter 58).

Treatment

The optimal treatment of HIV-associated PAH is unclear.³³⁰ Small studies have reported improved functional and hemodynamic parameters in patients with HIV and PAH during treatment with epoprostenol and bosentan.³³¹ Other treatments such as sildenafil and iloprost may also be useful.^{332,333} Epoprostenol may be associated with intravascular infections in the HIV-infected population, and high levels of

sildenafil can be seen when used in combination with anti-retrovirals, particularly ritonavir. Although still controversial, some studies have found a benefit in treating patients with ART or the combination of ART and bosentan.^{317,334}

OBSTRUCTIVE LUNG DISEASE

Frequently, obstructive lung disease develops in HIV-infected individuals, and a variety of pulmonary function test abnormalities are seen.³³⁵ Prior to ART, the PCHIS researchers performed serial pulmonary function tests in more than 1100 HIV-infected individuals and demonstrated that advanced HIV infection, characterized by a CD4⁺ lymphocyte count less than 200 cells/ μ L or HIV-associated symptoms, as well as race, cigarette smoking, and intravenous drug use, were associated with reductions in *diffusing capacity for carbon monoxide* (DL_{CO}).³³⁶ A PCHIS multivariable analysis found that both PCP and bacterial pneumonia were independently associated with an accelerated decline in the *forced vital capacity* (FVC), *forced expiratory volume in 1 second* (FEV₁), FEV₁/FVC, and DL_{CO}.³³⁷ Several studies have found that significant proportions of HIV-infected individuals report respiratory symptoms and have abnormal pulmonary function testing including decreases in forced expiratory flow rates, significant response to bronchodilators, and impairment of DL_{CO}.^{146,338-343} Impairment in FEV₁ in HIV-infected individuals is associated with decreased health status.^{343a,b} Impairments in DL_{CO} have been reported in HIV-infected individuals without a history of smoking,³⁴⁴ and data from multicenter studies of HIV-infected individuals and non-HIV-infected controls found that HIV was an independent risk factor for decreased DL_{CO}.^{345,346}

HIV-infected individuals may have asthma that precedes their HIV infection or that develops after the onset of HIV. HIV-infected patients are more likely than non-HIV-infected patients to have bronchial hyperresponsiveness to methacholine.³⁴² In one clinic-based study, a history of asthma was reported in 21% and current asthma in 17% of 136 patients attending a primary care clinic for HIV infection.³⁴⁷ Another study found that physician-diagnosed asthma was present in 21% of participants and bronchodilator responsiveness was present in 9%.³⁴⁸ CD4⁺ lymphocyte counts greater than 200 cells/ μ L are associated with current asthma in those with HIV infection,³⁴⁷ and one report has linked use of asthma medication to ART use in HIV-infected children, suggesting that immune responses are important, but this association has not been replicated in all cohorts.^{348,349} Other factors such as female sex and obesity have also been found to be associated with asthma in HIV-infected individuals.³⁴⁸

Obstructive airway disease, chronic bronchitis, and bronchiectasis are well-recognized sequelae of opportunistic infection,^{350,351} although evidence also suggests that HIV infection is associated with an increase in emphysema/COPD apart from the effects of opportunistic infections.³⁵² Data from a large cohort of HIV-infected and non-HIV-infected military veterans have demonstrated that HIV infection is an independent risk factor for COPD prevalence and incidence by self-report and *International Classification of Diseases*, Ninth revision diagnosis.^{272,353} The role of ART in COPD is unclear and may depend on the population studied. Two studies have found increased airway obstruction

in HIV-infected individuals receiving ART,^{344,354} but other groups have found that a high HIV RNA level is associated with a more rapid decline in FEV₁ and a greater prevalence of obstructive lung disease.³³⁸⁻³⁴⁰

Treatment

In general, treatment of asthma and COPD should be similar to that for the non-HIV-infected population (Chapters 42 and 44). PIs, particularly ritonavir, have been reported to increase systemic levels of inhaled or intranasal fluticasone, leading to Cushing syndrome or adrenal suppression when corticosteroids are tapered.³⁵⁵ Use of high-dose inhaled steroids for COPD in individuals with HIV also requires careful monitoring for oral candidiasis and bacterial pneumonia.³⁵⁶

INTERSTITIAL PNEUMONITIDES

Although opportunistic infection and neoplasia dominate the clinical spectrum of HIV-associated pulmonary diseases, a small number of patients present with signs and symptoms that are attributable to one of the interstitial pneumonitides, *lymphocytic interstitial pneumonitis* (LIP) or *nonspecific interstitial pneumonitis* (NSIP).³⁵⁷

Lymphocytic Interstitial Pneumonitis

Described by Carrington and Liebow more than 30 years ago, it remains speculative whether LIP is a pathogenically distinct entity or a disorder of multiple causes that produce a similar pathologic reaction (Chapter 63).

Clinical Features. The most striking feature of HIV-associated LIP is the effect of age on its incidence. Early in the AIDS epidemic, one third to one half of AIDS-defining diagnoses in HIV-infected children in high-income, industrialized countries were due to LIP. In contrast, LIP is rare in adults.³⁵⁸

The chest radiograph presentation of LIP is nonspecific (Fig. 90-11) and is characterized by bilateral reticulonodular interstitial opacities with a middle to lower lung zone predominance.³⁵⁹ Areas of alveolar opacity that are thought to result from bronchial compression caused by more severe lymphocytic infiltration are rare. Hilar or mediastinal adenopathy is occasionally seen. Chest CT scans may reveal small (2- to 4-mm) nodules, often in a peribronchovascular distribution (eFig. 90-40), or diffuse areas of ground-glass opacity.³⁶⁰

Diagnosis and Treatment. The definitive diagnosis of LIP requires histologic confirmation by biopsy. There are so few studies of LIP among HIV-infected adults that neither definitive therapy nor benefit of therapy has been determined. Cases of LIP that responded to ART alone have been reported.^{358,361}

Nonspecific Interstitial Pneumonitis

NSIP is a pulmonary disorder characterized histologically by infiltration of mononuclear cells, predominantly lymphocytes and plasma cells, into the peribronchiolar and perivascular interstitium (Chapter 63). NSIP has been reported with various frequencies in HIV-infected patients. Because it is a histologic diagnosis, its incidence depends on

Figure 90-11 Lymphocytic interstitial pneumonitis. Frontal chest radiograph of an HIV-infected patient showing diffuse reticulonodular infiltration. Biopsy specimen revealed lymphocytic interstitial pneumonitis.

the frequency with which biopsy is performed during the diagnostic evaluation.

Clinical Features. The clinical features of NSIP are indistinguishable from those of PCP; however, NSIP may present at CD4⁺ lymphocyte counts greater than 200 cells/ μ L, whereas PCP rarely ($\leq 5\%$) does. For example, in a series of 67 HIV-infected patients with NSIP, the mean CD4⁺ lymphocyte count in the patients with NSIP was 492 cells/ μ L compared with 57 cells/ μ L for the matched control subjects with PCP.³⁶² The chest radiographic presentation of NSIP is usually a nonspecific diffuse interstitial pattern, which is also indistinguishable from that of PCP; however, one study reported that 16 of 36 (44%) patients with HIV-related NSIP had normal radiographs.³⁶³

Diagnosis and Treatment. The diagnosis of NSIP requires both histologic confirmation and the exclusion of other etiologies. The natural history of HIV-associated NSIP is poorly understood, but it usually resolves or stabilizes without therapy.³⁶² Observation is all that is required, but if the patient becomes severely ill, repeat bronchoscopy and biopsy are indicated to look for a different, usually infectious, disorder.

SARCOIDOSIS

Although sarcoidosis would seem an unlikely disorder among patients with HIV, a number of cases of sarcoidosis or sarcoid-like disease have been reported in this population. Many of these case reports have correlated the use of ART with the development of sarcoidosis.^{364,365} Whether sarcoidosis in HIV represents a manifestation of IRIS is debated. Approximately 75% of HIV-infected patients with sarcoidosis have CD4⁺ lymphocyte counts above 200 cells/ μ L.³⁶⁴

Both the clinical and imaging findings (eFig. 90-41) of sarcoidosis in HIV-infected patients mirror findings of sarcoidosis in non-HIV-infected patients.^{364,365} As described in Chapter 66, granulomatous inflammation of the lungs and other involved organs is characteristic. Stains and cultures of tissue should be obtained and, to diagnose sarcoid, must be negative for microorganisms (e.g., mycobacteria, fungi). Lymphocytic alveolitis with a high percentage of CD4⁺ lymphocytes may be encountered.³⁶⁶ Because no studies have evaluated treatment of sarcoidosis specifically in HIV-infected persons, until further data are available, management should follow guidelines as outlined for non-HIV-infected persons with sarcoidosis.

IMMUNE RECONSTITUTION INFLAMMATORY SYNDROME

IRIS describes a paradoxical worsening of clinical status related to recovery of the immune system following a period of immunosuppression. The syndrome typically develops after the initiation of ART in HIV-infected patients. IRIS is thought to result from the reconstitution of the immune system leading to host inflammatory responses to previously recognized or subclinical infections. Immune reconstitution may also result from an inflammatory or immune response to cancer or self antigens, because cases of IRIS have been reported to present with worsening tumor or autoimmune disease.³⁶⁷

Numerous disease processes have been associated with IRIS. These include many infections, sarcoidosis, autoimmune conditions, and tumors.^{368,369} Among infectious triggers, mycobacterial infections—particularly *M. tuberculosis* (eFig. 90-42) and MAC—are most frequently encountered. Fungal infections, including PCP and *Cryptococcus*, as well as viral infections, such as CMV, can also be exacerbated by IRIS. The majority of cases of IRIS are seen within the first 1 to 3 months following the initiation of ART, although cases may present several months after the initiation of ART.³⁶⁹ In most studies, IRIS is significantly associated with starting ART in close proximity to treatment for an acute opportunistic infection.^{370,371} Nonetheless, recent studies support starting ART concurrently or very soon after starting treatment of opportunistic infection, because this strategy results in improved survival.^{109-111,372} Recommendations regarding the exact timing of ART initiation depends on the patient's CD4⁺ cell count, type of infection or complication, and organ system involved.

In general, ART should be continued in patients who have IRIS, although careful review on a case-by-case basis is required and expert consultation is recommended.²⁹ Nonsteroidal anti-inflammatory agents can be used to decrease inflammation. Less commonly, steroids may be indicated if the excessive inflammatory response can be particularly harmful, for example in tuberculosis meningitis, or with other lesions that are life threatening, such as those involving the central nervous system or those causing airway compromise. Optimal dosage and duration have not been studied, but prednisone or methylprednisolone at approximately 1.5 mg/kg of body weight per day for 2 weeks followed by 0.75 mg/kg/day for an additional 2 weeks while monitoring clinical response may be used.²⁹

Key Points

- HIV infection results in immune dysregulation, dysfunction, and deficiency, with a progressive decline in the circulating CD4⁺ lymphocyte count, particularly in patients that are not receiving effective combination antiretroviral therapy (ART). HIV infection also causes alteration in several lines of host defense in the lungs and respiratory tract.
- The peripheral CD4⁺ lymphocyte count influences the risk for pulmonary complications in HIV-infected persons; as the CD4⁺ count decreases, the risk of opportunistic infections and HIV-associated malignancies increases progressively.
- Worldwide, tuberculosis is the most common infectious lung complication and a major cause of HIV-associated morbidity and mortality. Drug-resistant tuberculosis is increasing in incidence and seems to have a predilection for persons infected with HIV.
- Bacterial pneumonia and *Pneumocystis pneumonia* (PCP) are also common infectious lung complications associated with HIV; noninfectious conditions that may be encountered with increased frequency in patients with HIV include lung cancer, idiopathic pulmonary arterial hypertension, and chronic obstructive pulmonary diseases.
- The differential diagnosis for pulmonary diseases in HIV-infected patients is broad, and the clinical features and radiographic findings of many diseases may overlap significantly. Definitive diagnosis is highly recommended in patients with HIV. When feasible, early bronchoscopy with bronchoalveolar lavage should be performed in patients with pneumonia who do not have an established microbiologic diagnosis.
- In HIV-infected patients recently started on ART, immune reconstitution inflammatory syndrome may develop, presenting with paradoxical worsening of conditions that include infections (e.g., tuberculosis, *Mycobacterium avium* complex, and PCP), malignancies (e.g., Kaposi sarcoma), and inflammatory diseases (e.g., sarcoidosis).

eFigure 90-8 *Mycobacterium avium* complex endo-bronchial infection in an HIV-infected patient with a low CD4⁺ count. Bronchoscopic image shows small white nodular areas (*arrows*). Biopsy recovered *Mycobacterium avium* complex organisms. (Courtesy Michael Gotway, MD; case by Syed A.J. Zaidi, MBBS, FCCP, Pulmonary-Critical Care section, Maricopa Medical Center, Phoenix, AZ.)

eFigure 90-9 *Mycobacterium avium* complex lymphadenitis. **A**, Frontal chest radiograph in an HIV-infected patient with a CD4⁺ count less than 50 cells/ μ L shows bilateral hilar (*arrows*) and left mediastinal (*arrowhead*) lymphadenopathy. **B**, Axial enhanced chest CT confirms presence of enlarged aortopulmonary lymph nodes (*arrowhead*) as well as left tracheobronchial lymphadenopathy. Note the presence of low attenuation areas, consistent with necrosis. (Courtesy Michael Gotway, MD.)

eFigure 90-10 *Mycobacterium kansasii* pulmonary infection. Frontal chest radiograph performed in an HIV-infected patient with a CD4⁺ count less than 50 cells/ μ L shows linear bronchovascular thickening in the left upper lobe associated with left apical thin-walled cavities (*arrows*). (Courtesy Michael Gotway, MD.)

eFigure 90-11 Typical imaging appearance of *Pneumocystis jirovecii* pneumonia. Frontal chest radiograph in an HIV-infected patient with a CD4⁺ count less than 200 cells/ μ L shows bilateral, symmetric perihilar indistinctness. Sputum induction recovered *Pneumocystis jirovecii*. (Courtesy Michael Gotway, MD.)

Figure 90-12 Typical imaging appearance of *Pneumocystis jirovecii* pneumonia. **A**, Frontal chest radiograph in an HIV-infected patient with a CD4⁺ count less than 200 cells/ μ L shows bilateral, interstitial thickening with increased attenuation consistent with a ground-glass appearance (increased pulmonary attenuation without obscuration of the underlying vascular and bronchial margins). Sputum induction recovered *Pneumocystis jirovecii*. **B**, Axial chest CT displayed in lung windows shows the typical appearance of multifocal, bilateral ground-glass opacity in HIV-infected patients with *Pneumocystis jirovecii* pneumonia. (Courtesy Michael Gotway, MD.)

eFigure 90-13 Atypical imaging appearance of *Pneumocystis jirovecii* pneumonia. Frontal chest radiograph in an HIV-infected patient with a CD4⁺ count less than 200 cells/ μ L shows faint predominantly right perihilar bronchovascular indistinctness; minimal left perihilar indistinctness is present. Asymmetry or frankly unilateral pulmonary findings are an atypical imaging manifestation of *Pneumocystis jirovecii* pneumonia. Nevertheless, in an HIV-infected patient with a CD4⁺ count less than 200 cells/ μ L such an imaging appearance is suspicious for *Pneumocystis jirovecii* pneumonia. (Courtesy Michael Gotway, MD.)

eFigure 90-14 Imaging appearance of *Pneumocystis jirovecii* pneumonia: pneumatocele formation. **A,** Frontal chest radiograph in an HIV-infected patient with a CD4⁺ count less than 200 cells/ μ L shows bilateral mild bronchovascular thickening and indistinctness, consistent with *Pneumocystis jirovecii* pneumonia. A thin-walled right perihilar cyst (arrow) is present, consistent with a pneumatocele. **B,** Frontal chest radiograph in an HIV-infected patient with a CD4⁺ count less than 200 cells/ μ L shows innumerable bilateral linear, reticular, and cystic foci. **C,** Axial chest CT displayed in lung windows shows numerous, bilateral thin-walled cysts with a few areas of ground-glass opacity also visible. The appearance is somewhat reminiscent of Langerhans cell histiocytosis. **D,** Follow-up chest radiograph obtained several months after (A) shows resolution of the cysts. (Courtesy Michael Gotway, MD.)

eFigure 90-15 Imaging appearance of *Pneumocystis jirovecii* pneumonia: pneumothorax due to pneumatocele formation. **A**, Frontal chest radiograph in an HIV-infected patient with a CD4⁺ count less than 200 cells/ μ L shows bilateral pneumothoraces (*), on the right side tracking into the fissural surfaces (arrowhead). **B**, Axial chest CT displayed in lung windows in a different patient shows patchy bilateral ground-glass opacity, consistent with *Pneumocystis jirovecii* pneumonia, complicated by thin-walled cysts (arrows), representing pneumatoceles. A right-sided pneumothorax (*) is present. (Courtesy Michael Gotway, MD.)

eFigure 90-16 Atypical imaging appearance of *Pneumocystis jirovecii* pneumonia: focal consolidation. **A**, Frontal chest radiograph in an HIV-infected patient with a CD4⁺ count less than 200 cells/ μ L shows focal right upper lobe opacity (arrow), demarcated by the right horizontal fissure. **B**, Focused axial chest CT displayed in lung windows in a separate patient shows air space consolidation in the right middle lobe. Sputum induction recovered *Pneumocystis jirovecii* in both patients. (Courtesy Michael Gotway, MD.)

eFigure 90-17 Frontal chest radiograph in an HIV-infected patient with a CD4⁺ count less than 200 cells/ μ L shows patchy bilateral opacities consistent with *Pneumocystis jirovecii* pneumonia. The more focal left mid-lung opacity (arrow) raises the possibility of a second, superimposed process, but no other organisms could be recovered and the pulmonary abnormalities resolved with treatment of *Pneumocystis jirovecii*. (Courtesy Michael Gotway, MD.)

eFigure 90-18 Atypical imaging appearance of *Pneumocystis jirovecii* pneumonia: focal lung opacity. Axial chest CT displayed in lung windows performed in an HIV-infected patient with a CD4⁺ count less than 200 cells/ μ L shows air-space consolidation in the right upper lobe. Patchy left upper lobe ground-glass opacity is also present, consistent with *Pneumocystis jirovecii* pneumonia. The patient underwent transthoracic percutaneous lung biopsy of the focal opacity to exclude the possibility of a second process superimposed on *Pneumocystis jirovecii* pneumonia; this biopsy showed only *Pneumocystis jirovecii* organisms. (Courtesy Michael Gotway, MD.)

eFigure 90-19 Atypical imaging appearance of *Pneumocystis jirovecii* pneumonia: focal nodules. **A**, Frontal chest radiograph in an HIV-infected patient with a CD4⁺ count less than 200 cells/ μ L shows faint left mid-lung nodular opacity (arrows). **B**, Axial chest CT displayed in lung windows shows two focal lingular nodules. Transthoracic percutaneous lung biopsy showed only *Pneumocystis jirovecii* organisms. (Courtesy Michael Gotway, MD.)

eFigure 90-20 Atypical imaging appearance of *Pneumocystis jirovecii* pneumonia: upper lobe predominant pulmonary opacity. **A**, Frontal chest radiograph in an HIV-infected patient with a CD4⁺ count less than 200 cells/ μ L shows bilateral, right-greater-than-left, upper lobe opacities. **B** and **C**, Given the atypical chest radiographic findings, the patient underwent axial chest CT, displayed in lung windows, due to continued suspicion for *Pneumocystis jirovecii* pneumonia, which shows bilateral upper lobe consolidation and less pronounced bibasal ground-glass opacity. Bronchoscopy recovered *Pneumocystis jirovecii*. (Courtesy Michael Gotway, MD.)

eFigure 90-21 Cryptococcal pulmonary infection: interstitial appearance. Frontal chest radiograph in an HIV-infected patient with a low CD4⁺ count shows bilateral, right-greater-than-left, perihilar ground-glass attenuation and linear, interstitial thickening, suspicious for *Pneumocystis jirovecii* pneumonia; however, the opacities were proven to be the result of cryptococcal pulmonary infection. (Courtesy Michael Gotway, MD.)

eFigure 90-22 Cryptococcal pulmonary infection: focal pulmonary opacity. Frontal chest radiograph in an HIV-infected patient with a low CD4⁺ count shows focal right lower lobe consolidation superimposed on more diffuse interstitial thickening throughout the right lung. (Courtesy Michael Gotway, MD.)

eFigure 90-23 Cryptococcal pulmonary infection: pulmonary nodule. Frontal chest radiograph in an HIV-infected patient with a low CD4⁺ count shows a right suprahilar pulmonary nodule (arrow). Transthoracic percutaneous lung biopsy demonstrated cryptococcal infection. (Courtesy Michael Gotway, MD.)

eFigure 90-24 Cryptococcal pulmonary infection: thoracic lymphadenopathy and nodules. **A**, Frontal chest radiograph in an HIV-infected patient with a low CD4⁺ count shows right hilar lymph node enlargement (*arrow*). **B–D**, Axial chest CT displaced in soft tissue (**B**) and lung (**C** and **D**) windows confirms right peribronchial lymph node enlargement (*arrowhead*, **B**) and shows a nodule in the right lower lobe (*arrows*, **B** and **C**); note the tiny focus of cavitation evident within the nodular anteriorly in (**B**). A separate cavitary nodule (*arrowhead*, **D**), with surrounding satellite opacities, is seen slightly more inferiorly in the superior segment of the right lower lobe. (Courtesy Michael Gotway, MD.)

eFigure 90-25 Cryptococcal pulmonary infection: miliary infection. Frontal chest radiograph performed in an HIV-infected patient with a low CD4⁺ count shows numerous symmetrical bilateral small pulmonary nodules. (Courtesy Michael Gotway, MD.)

eFigure 90-26 *Coccidioides immitis* pulmonary infection: miliary infection. **A**, Frontal chest radiograph in an HIV-infected patient with a low CD4⁺ count shows numerous symmetrical bilateral small pulmonary nodules. **B**, Axial chest CT shows numerous bilateral pulmonary nodules, consistent with a random small nodular, or miliary, pattern. Bronchoscopy with transbronchial biopsy proved *Coccidioides immitis* infection. (Courtesy Michael Gotway, MD.)

eFigure 90-27 *Aspergillus* pulmonary infection. **A**, Frontal chest radiograph in an HIV-infected patient with a low CD4⁺ count shows right upper lobe cystic lesions (arrows) with surrounding small nodules and left superior mediastinal soft tissue (arrowheads). Axial chest CT displayed in lung (**B**) and soft tissue (**C**) windows shows a right apical cavity (arrow, **B**) and a necrotic mass in the left superior mediastinum (arrowheads, **C**) invading the chest wall anteriorly. Transthoracic percutaneous lung biopsy of the left-sided mass recovered *Aspergillus fumigatus*. (Courtesy Michael Gotway, MD.)

eFigure 90-28 *Aspergillus* pulmonary infection. **A**, Focused frontal chest radiograph in an HIV-infected patient with a low CD4⁺ count shows an irregular cavity (arrowheads) in the right apex. **B**, Axial chest CT displayed in lung windows shows a complex cavity with internal opacity (arrowheads) as well as right apical lung nodules (arrows). **C**, Postmortem right lung specimen shows a necrotic right apical cavity with complex internal material, correlating with the CT findings. Numerous areas of arterial and venous invasion with thrombosis and infarction were identified, and *Aspergillus fumigatus* was recovered from the material within the cavity. (Modified from Gotway MB, Dawn SK, Caoili EM, et al: The radiologic spectrum of pulmonary *Aspergillus* infections. *J Comput Assist Tomogr* 26:159–173, 2002.)

eFigure 90-29 Cytomegalovirus infection. Axial chest CT in an HIV-infected patient with a low CD4⁺ count shows patchy, variably-sized pulmonary nodular opacities. The imaging features are very nonspecific. (Courtesy Michael Gotway, MD.)

eFigure 90-30 *Strongyloides stercoralis* pulmonary infection. **A**, Frontal chest radiograph in an HIV-infected patient with a low CD4⁺ count shows nonspecific bilateral areas of linear opacity and interstitial thickening, predominating in the perihilar regions. **B**, Axial chest CT displayed in lung windows shows patchy, multifocal, bilateral areas of ground-glass opacity associated with mild linear and reticular opacities. **C**, Surgical lung biopsy recovered *Strongyloides stercoralis* organisms. (**A** and **B**, Courtesy Michael Gotway, MD.)

eFigure 90-31 Pulmonary Kaposi sarcoma: typical imaging appearance. **A**, Frontal chest radiograph in an HIV-infected patient with a low CD4⁺ count shows multifocal, bilateral, perihilar bronchovascular thickening and nodularity. **B–D**, Axial chest CT displayed in lung windows shows patchy multifocal peribronchovascular nodular thickening (arrowheads). Note the presence of some patchy peribronchovascular ground-glass opacity (left upper lobe in **A** and **B**). (Courtesy Michael Gotway, MD.)

eFigure 90-32 Pulmonary Kaposi sarcoma: atypical imaging appearance. **A**, Frontal chest radiograph in an HIV-infected woman with cardiomyopathy and a low CD4⁺ count shows cardiomegaly and a faint peripheral left lung nodular opacity (arrow). **B**, Frontal chest radiograph 8 months after (**A**) shows growth in the peripheral left lung opacity (arrow). **C**, Axial chest CT displayed in lung windows performed at the time of (**B**) shows a subpleural, superior segment left lower lobe nonspecific nodule (arrowhead); this nodule was not calcified. Percutaneous transthoracic fine needle aspiration and core lung biopsy was performed, but was nondiagnostic. Surgical lung biopsy subsequently proved Kaposi sarcoma. (Courtesy Michael Gotway, MD.)

eFigure 90-33 Non-Hodgkin lymphoma in HIV infection: solitary nodule/mass. **A**, Frontal chest radiograph in an HIV-infected patient with a low CD4⁺ count shows an ill-defined left upper lobe nodule (*arrow*). **B**, Frontal chest radiograph obtained three months following (**A**) after presumptive anti-microbial therapy shows that the left upper lobe lesion (*arrow*) has grown into a mass. **C**, Axial chest CT displayed in lung windows shows a poorly defined peripheral left upper lobe mass. Percutaneous transthoracic fine-needle aspiration and core lung biopsy showed non-Hodgkin lymphoma. (Courtesy Michael Gotway, MD.)

eFigure 90-34 Non-Hodgkin lymphoma in HIV infection: multiple nodules. Axial chest CT performed in an HIV-infected patient with a low CD4⁺ count displayed in lung windows shows two circumscribed, minimally lobulated left upper lobe nodules proven by percutaneous transthoracic fine-needle aspiration and core lung biopsy to be due to non-Hodgkin lymphoma. (Courtesy Michael Gotway, MD.)

eFigure 90-35 Non-Hodgkin lymphoma in HIV infection: pulmonary mass. Axial chest CT performed in an HIV-infected patient with a low CD4⁺ count displayed in soft tissue windows shows a left lower lobe soft tissue mass proven by percutaneous transthoracic fine-needle aspiration and core lung biopsy to be due to non-Hodgkin lymphoma. An additional tumor nodule (*arrow*) is also present. (Courtesy Michael Gotway, MD.)

eFigure 90-36 Non-Hodgkin lymphoma in HIV infection: small nodules in a perilymphatic distribution. A–C, Axial chest CT performed in an HIV-infected patient with a low CD4⁺ count displayed in lung windows shows innumerable small, well-defined nodules distributed along the fissures (*double arrowheads, B*), in the centrilobular region (*black arrowhead, A*), and along mildly thickened interlobular septae (*white arrowhead, C*). These nodules are located in the regions of pulmonary lymphatics; this small nodular pattern is referred to as a perilymphatic nodule distribution at high-resolution CT. Bronchoscopy with transbronchial biopsy showed that these nodules were due to non-Hodgkin lymphoma. (Courtesy Michael Gotway, MD.)

eFigure 90-37 Primary effusion lymphoma in HIV infection. **A**, Frontal chest radiograph in an HIV-infected patient with a low CD4⁺ count shows a right pleural effusion and moderate, right-greater-than-left linear interstitial thickening. **B**, Axial enhanced chest CT displayed in soft tissue windows shows bilateral pleural effusions; trace pleural thickening (*arrowheads*) may be present on the right. Thoracentesis showed the presence of lymphoma. (Courtesy Michael Gotway, MD.)

eFigure 90-38 Multicentric Castleman disease in HIV infection. **A–C**, Axial enhanced chest CT displayed in soft tissue windows performed in an HIV-infected patient with a low CD4⁺ count shows bilateral, mildly enhancing axillary lymphadenopathy (*arrowheads*), proven to reflect Castleman disease on excision. (Courtesy Michael Gotway, MD.)

eFigure 90-39 Bronchogenic carcinoma in HIV infection. **A**, Axial enhanced chest CT shown in soft tissue and **B**, lung windows shows two bronchogenic carcinomas in patients with HIV infection. The right lower lobe mass (**A**) represented large cell malignancy; the cavitary left upper lobe lesion (**B**) represented squamous cell carcinoma. (Courtesy Michael Gotway, MD.)

eFigure 90-40 Lymphocytic interstitial pneumonia in HIV infection. Axial chest CT displayed in lung windows in a child with HIV infection shows multiple circumscribed small nodules proven on transbronchial biopsy to represent lymphocytic interstitial pneumonia. (Courtesy Michael Gotway, MD.)

eFigure 90-41 Sarcoidosis in HIV infection. **A**, Frontal chest radiograph in an HIV-infected patient with a CD4⁺ count greater than 200 cells/ μ L shows bilateral symmetrical hilar lymphadenopathy (arrows). **B**, Axial enhanced chest CT displayed in soft tissue windows shows bilateral lymph node enlargement (arrows). **C** and **D**, Chest CT displayed in lung windows shows the upper lobe predominant perilymphatic nodules (arrowheads) typical of sarcoidosis. (Courtesy Michael Gotway, MD.)

eFigure 90-42 Immune reconstitution inflammatory syndrome. **A**, Frontal chest radiograph appears normal in an HIV-infected patient with a low CD4⁺ count, in whom *Mycobacterium tuberculosis* was recently diagnosed. **B**, Frontal chest radiograph performed 2 months following institution of combination antiretroviral therapy shows development of right paratracheal lymphadenopathy (arrow). (Courtesy Michael Gotway, MD.)

PULMONARY COMPLICATIONS OF STEM CELL AND SOLID ORGAN TRANSPLANTATION

DAVID K. MADTES, MD

INTRODUCTION
INFECTIOUS COMPLICATIONS
Bacterial

Viral
Fungal

NONINFECTIOUS COMPLICATIONS
Early Complications
Late Complications

INTRODUCTION

Stem cell transplantation (SCT) is the only known curative treatment for many patients with life-threatening hematologic and solid tumor malignancies. Likewise, *solid organ transplantation* (SOT) provides life-saving treatment for many patients with end-stage organ disease. Approximately 20,000 SCT and 28,000 SOT procedures are performed each year in the United States.^{1,2} These patients are at constant risk for opportunistic infections, drug-related pulmonary toxicities, and malignancies due to their chronic state of immune suppression.³⁻⁶ The aim of this chapter is to review the infectious and noninfectious pulmonary complications of stem cell and solid organ transplantation with a focus on the diagnostic and therapeutic challenges presented by these patients.

INFECTIOUS COMPLICATIONS

Despite effective prophylaxis strategies, infections in the lower respiratory tract remain a common life-threatening complication. The risk of infection is primarily determined by epidemiologic exposures of the donor and recipient and “the net state of immune suppression.”⁷ The spectrum of microorganisms responsible for posttransplantation infections is similar among SCT and SOT recipients, and the infections follow a fairly characteristic pattern. [Figures 91-1](#) and [91-2](#) show timelines for the pulmonary complications, both infectious and noninfectious, following SCT and SOT, respectively.

The *first phase* of infection risk is considered the first month after transplant. For SCT recipients, infectious risks in the first month are due to neutropenia and immune suppression related to the development of acute *graft-versus-host disease* (GVHD) and its treatment. Conventional nosocomial infections with gram-positive and gram-negative bacteria, as well *herpes simplex virus* (HSV) and *Candida* species, predominate. For SOT recipients, during the first month posttransplantation, infectious risks are predominantly related to surgery and intensive care, along with the initiation of immunosuppressive therapy.

The *second phase* of infection risk extends from 1 to 6 months during the period of maximum immunosuppression prescribed to treat GVHD in SCT patients or to avoid

acute allograft rejection in SOT recipients. This interval is characterized by the emergence of opportunistic pathogens. The *third phase* of infection risk is after 6 months when immunosuppressive therapy can be decreased in the majority of patients. Infections during this phase are predominantly due to community-acquired organisms and, to a lesser extent, opportunistic pathogens.

Previously common pathogens such as *Pneumocystis jirovecii* (PCP) and *cytomegalovirus* (CMV) are now less common due to routine use of antimicrobial prophylaxis. However, prophylactic antimicrobials and nosocomial exposures have contributed to the emergence of antimicrobial-resistant pathogens such as *Stenotrophomonas* species, mucormycosis, and ganciclovir-resistant CMV.⁸ In addition, improved microbiologic diagnostic techniques have allowed the recognition of previously undiagnosed infections.⁸

The lung is the leading site of infection in lung and heart transplant recipients⁹⁻¹³ and is the second most common site in liver transplant recipients.¹⁴ In a retrospective, multicenter study of 236 lung transplant recipients, pneumonia was reported in 25.8% of recipients. The microbiologic etiology was established in 57 (67%) of the cases. Of the microbiologically proven cases, 82.7% were bacterial, 14% were fungal, and 10.3% were due to viruses.¹³

Given the broad spectrum of pathogens that cause pneumonia in transplant recipients and the potential for complications from empiric antibiotics, it is important to identify the causative organisms whenever possible. Bronchoscopy is the procedure of choice in most transplant recipients. The diagnostic yield of bronchoscopy in SCT recipients is reported to range from 42% to 65%¹⁵⁻²¹ and is highest when performed before the initiation of antimicrobials¹⁵ and within 24 hours of presentation.¹⁶ Likewise, in SOT recipients, the diagnostic yield of bronchoscopy ranges from 30% to 72% and is highest when performed for pulmonary opacities within the first 6 months of transplantation.^{20,22-28} The recommended laboratory evaluation of bronchoscopic specimens for specific pathogens in the lower respiratory tract of transplant recipients is listed in [eTable 91-1](#).

BACTERIAL

Bacterial pneumonia after transplantation can be either nosocomial or community acquired with each mode having a characteristic time of onset, causative organisms, and

e-Table 91-1 Routine Laboratory Evaluation of Bronchoalveolar Lavage Specimens for Specific Infectious Pulmonary Complications after Transplantation (see also Chapter 17)

PATHOLOGY

- Stains
 - Wright-Giemsa stain
 - Papanicolaou stain
 - Silver stain
 - Modified Jimenez stain (or other stain suitable for *Legionella* species)
 - Direct fluorescent antibody stain for *Pneumocystis*

MICROBIOLOGY

- Stains
 - Gram stain
 - Wet mount potassium hydroxide or calcofluor white stain
 - Acid-fast
 - Modified acid-fast stain
 - Fluorescent antibody stain for *Legionella* species
- Culture
 - Bacterial (aerobic), semiquantitative culture method
 - Fungal
 - *Legionella* species (chocolate yeast extract)
 - Acid-fast
 - Nocardia
 - Actinomyces
- Immunoassay
 - Galactomannan ELISA assay for *Aspergillus*
 - Urinary *Legionella* antigen (depends on renal function; only detects antigen of *Legionella pneumophila* serogroup 1)
- Molecular diagnostics
 - PCR assay for *Aspergillus*, *Chlamydia*, *Mycoplasma*

VIROLOGY

- Direct fluorescence staining with antibodies against CMV, RSV, HSV, VZV, influenza, parainfluenza, adenovirus
- Molecular diagnostics
- PCR or reverse transcription-PCR for RSV, influenza A & B, parainfluenza, human metapneumovirus, rhinovirus, bocavirus, adenovirus, rhinovirus, coronavirus
- Culture
 - Rapid centrifugation (shell vial) culture for CMV, RSV
 - Routine viral culture

CMV, cytomegalovirus; ELISA, enzyme-linked immunosorbent assay; HSV, herpes simplex virus; RSV, respiratory syncytial virus; VZV, varicella-zoster virus.

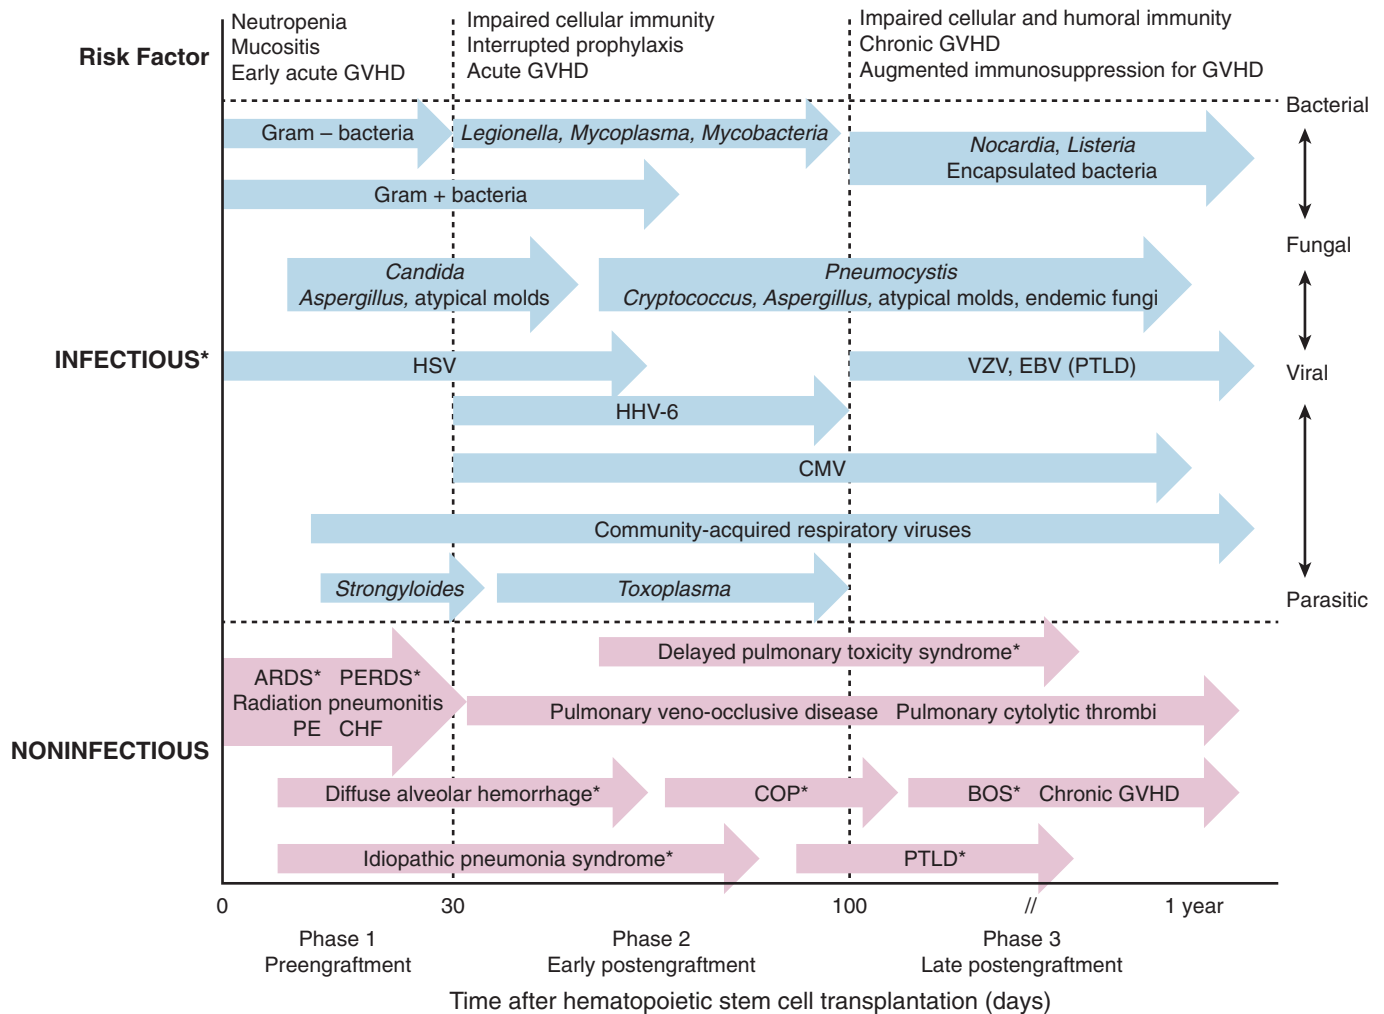

Figure 91-1 Timeline of infectious and noninfectious pulmonary complications following stem cell transplantation. ARDS, acute respiratory distress syndrome; COP, bronchiolitis obliterans organizing pneumonia/cryptogenic organizing pneumonia; BOS, bronchiolitis obliterans syndrome; CHF, congestive heart failure; CMV, cytomegalovirus; EBV, Epstein-Barr virus; GVHD, graft-versus-host disease; HSV, herpes simplex virus; HHV-6, human herpes virus-6; PE, pulmonary embolism; PERDS, peri-engraftment respiratory distress syndrome; PTLD, posttransplant lymphoproliferative disorder; VZV, varicella-zoster virus. *Consider diagnostic bronchoscopy to (1) establish or rule out an infectious etiology and/or to (2) diagnose a noninfectious process. (Adapted from Soubani AO: Respiratory infections following hematopoietic stem cell transplantation. In Agusti C, Torres A, editors: Pulmonary infection in the immunocompromised patient: strategies for management. West Sussex, UK, 2009, Wiley-Blackwell, pp 213–256 and from Afessa B, Peters SG: Chronic non-infectious pulmonary complications in hematopoietic stem cell transplantation. In Agusti C, Torres A, editors: Pulmonary infection in the immunocompromised patient: strategies for management. West Sussex, UK, 2009, Wiley-Blackwell, pp 257–284 and from Harris B, Lowy FD, Stover DE, Arcasoy SM: Diagnostic bronchoscopy in solid-organ and hematopoietic stem cell transplantation. *Ann Am Thorac Soc* 10(1):39–49, 2013.)

outcome. Bacterial pneumonia develops in 21% to 38% of lung transplant,^{11–13} 5% to 34% of liver transplant,^{29,30} 11% to 19% of heart transplant,^{10,22,31} and 4% to 7% of renal transplant recipients.^{25,28,32,33} The most frequently documented bacterial pathogens in lower respiratory tract infections (LRTI) after SOT are gram-negative organisms, including *Pseudomonas* (eFig. 91-1), *Klebsiella*, *Escherichia*, *Legionella*, *Acinetobacter*, and *Stenotrophomonas*, as well as gram-positive bacteria such as *Staphylococcus*, *Corynebacterium*, and *Enterococcus*. Anaerobic infections are rare.^{12,13,29,34,35}

Although the precise incidence of bacterial pneumonia after SCT is difficult to ascertain due to the frequent use of empiric broad-spectrum antibiotics in the early posttransplant period, bacterial pneumonia has been reported in 7% to 11% of allogeneic and 5% to 15% of autologous SCT recipients.^{36–38} The most common bacterial pathogens

include *Escherichia*, *Pseudomonas*, *Klebsiella pneumoniae*, *Staphylococcus aureus*, and *Streptococcus pneumoniae*.^{38,39} Late-onset bacterial pneumonia, defined as beyond day 100 posttransplant, is frequently due to *K. pneumoniae*, *Pseudomonas*, *S. pneumoniae*, and *Staphylococcus* species.⁴⁰

The prevalence of active tuberculosis following SCT has been estimated to be 0.23% to 0.79%,^{41,42} whereas the prevalence ranges 0.5% to 15% for SOT recipients depending on the prevalence of tuberculosis in the general population.⁴³ The median time to tuberculosis onset is 9 months (range, 0.5 to 13 months), although the disease can arise as late as 2 years after transplantation.^{44,45} First-line antituberculosis therapy in transplant recipients generally includes isoniazid, pyrazinamide, and ethambutol.⁴³ Rifampin is generally avoided due to its ability to induce cytochrome P450 isoenzymes resulting in decreased serum concentrations of several immunosuppressants, including cyclosporine,^{45,46}

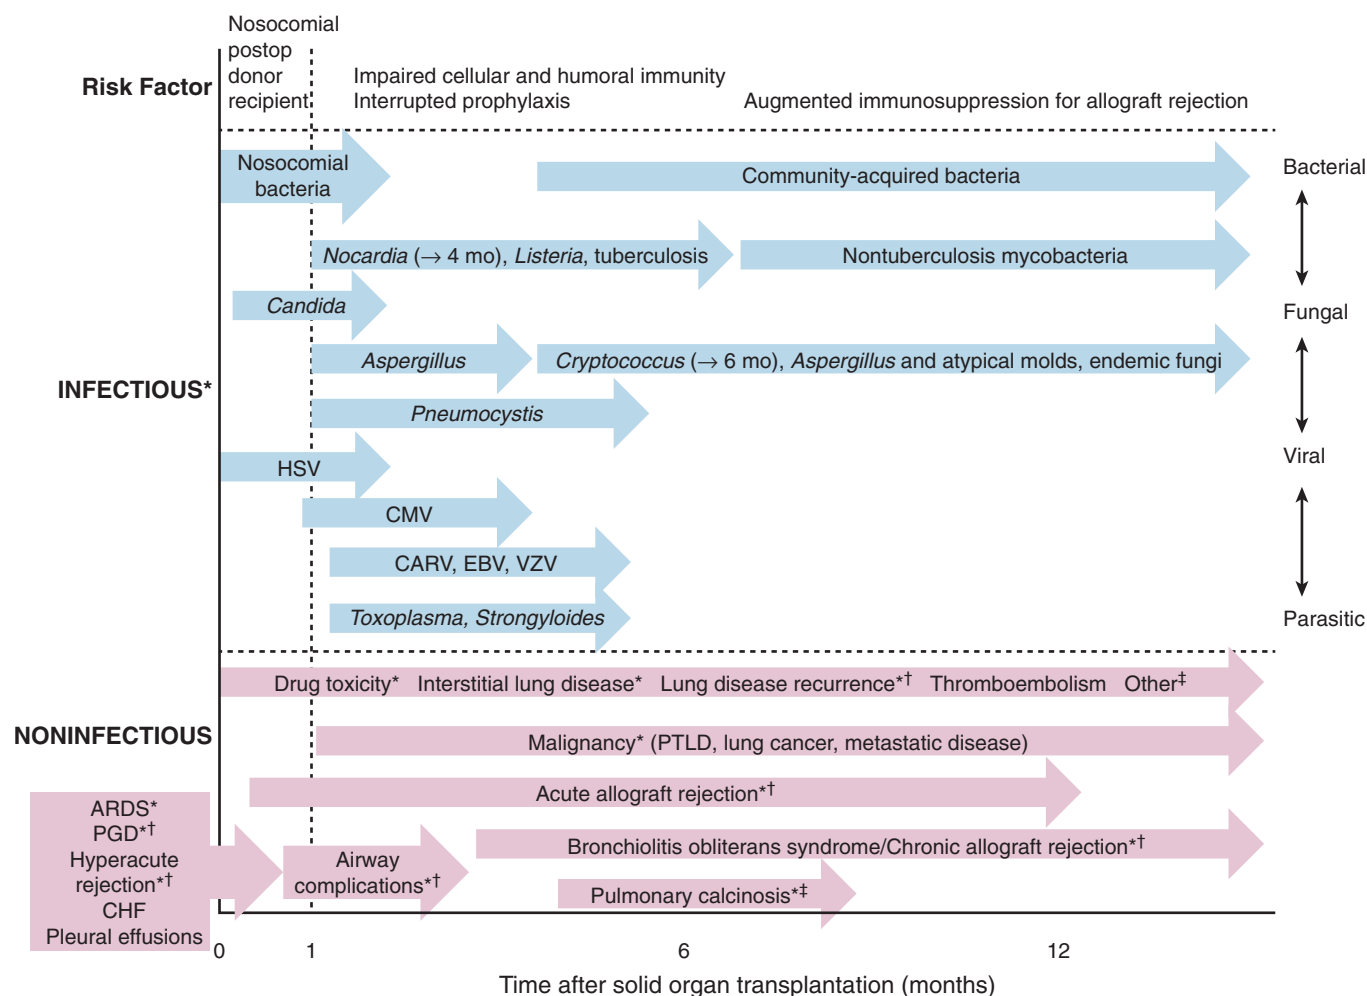

Figure 91-2 Timeline of infectious and noninfectious pulmonary complications following solid organ transplantation. ARDS, acute respiratory distress syndrome; CARV, community-acquired respiratory viruses; CHF, congestive heart failure; CMV, cytomegalovirus; EBV, Epstein-Barr virus; HSV, herpes simplex virus; PGD, primary graft dysfunction; PTLD, posttransplant lymphoproliferative disorder; VZV, varicella-zoster virus. *Consider diagnostic bronchoscopy to (1) establish or rule out an infectious etiology; (2) diagnose a noninfectious etiology, such as acute allograft rejection, malignancy, or interstitial lung disease; or (3) inspect bronchial anastomoses and other airway abnormalities. †Lung transplant recipients only. ‡Diagnostic bronchoscopy is warranted for pulmonary metastatic calcinosis for atypical presentations on imaging in renal transplant recipients. (Adapted from Harris B, Lowy FD, Stover DE, Arcasoy SM: Diagnostic bronchoscopy in solid-organ and hematopoietic stem cell transplantation. *Ann Am Thorac Soc* 10(1):39–49, 2013; based on data from Fishman JA: Infection in solid-organ transplant recipients. *N Engl J Med* 357:2601–2614, 2007)

tacrolimus,⁴⁷ sirolimus,^{48,49} everolimus,⁵⁰ and mycophenolate mofetil,^{51,52} which could result in allograft rejection. Interactions between common antimicrobial agents and immunosuppressants used in transplantation patients are listed in [eTable 91-2](#).

VIRAL

SCT and SOT recipients are vulnerable to two categories of viral infections: opportunistic viruses, especially herpesviruses, and community-acquired respiratory viruses. Opportunistic viruses responsible for pulmonary disease posttransplantation include CMV, HSV, *varicella zoster virus* (VZV), and *Epstein-Barr virus* (EBV). In the era of early detection and prophylactic or preemptive treatment, the incidence of CMV pneumonia is 4% to 32% for lung ([eFigs. 91-2](#) and [91-3](#)),⁵³⁻⁵⁸ 0% to 9.2% for liver,⁵⁹⁻⁶² 0.8% to 6.6% for heart,^{63,64} and less than 1% for kidney ([eFig. 91-4](#)) transplant recipients.⁶⁵ The incidence rate of CMV pneumonia

after SCT ([eFig. 91-5](#)) is 2% to 6%.^{40,66,67} CMV infection traditionally develops within the first 3 months after SCT and SOT; however, the use of antiviral prophylaxis has delayed its onset until after prophylaxis has been discontinued.

Current guidelines for diagnosis and management of CMV in SCT and SOT recipients support the use of either detection of pp65 antigen via immunoassay or quantitative *polymerase chain reaction* (PCR) for the recognition of CMV infection in serum or *bronchoalveolar lavage* (BAL).⁶⁸⁻⁷⁰ There are two accepted strategies for the prevention of CMV disease in transplant recipients: (1) universal prophylaxis in which antivirals are administered to all posttransplantation patients at risk and (2) preemptive therapy in which at-risk patients are monitored for viral replication and antivirals are initiated at a predetermined level of virus replication.^{68,69,71,72} Intravenous (IV) ganciclovir is recommended for the treatment of severe CMV disease, whereas oral valganciclovir is an alternative in less severe cases.^{68,69}

e-Table 91-2 Antimicrobial Agent Interactions with Immunosuppressants Used in Transplantation

Immunosuppressant	Antimicrobial Agent	Effect on Immunosuppressant	Reference
Cyclosporine	Chloramphenicol	↑ Concentrations	344
	Clarithromycin	↑ Concentrations	345
	Erythromycin	↑ Concentrations	344, 346
	Rifampin	↓ Concentrations	45, 46
	Trimethoprim	↓ Concentrations	151
	Ketoconazole	↑ Concentrations, 3×	125
	Fluconazole	↑ Concentrations	126
	Itraconazole	↑ Concentrations, 2×	127
	Voriconazole	↑ Concentrations, 1.7×	128
Tacrolimus	Posaconazole	↑ Concentrations, 2×	129, 130
	Chloramphenicol	↑ Concentrations	47, 344
	Erythromycin	↑ Concentrations	47
	Clarithromycin	↑ Concentrations	47
	Clotrimazole	↑ Concentrations	47
	Rifampin	↓ Concentrations	47
	Ketoconazole	↑ Concentrations	131, 132
	Fluconazole	↑ Concentrations	133
	Itraconazole	↑ Concentrations	134, 135
Sirolimus	Voriconazole	↑ Concentrations, 3×	125
	Posaconazole	↑ Concentrations, 4.5×	130
	Erythromycin	↑ Concentrations, 5×	48, 347
	Clarithromycin	↑ Concentrations	348
	Rifampin	↓ Concentrations	48
	Ketoconazole	↑ Concentrations	48, 136
	Fluconazole	↑ Concentrations	137, 138
Everolimus	Itraconazole	↑ Concentrations	139
	Voriconazole	↑ Concentrations, 11×	140, 141
	Erythromycin	↓ Clearance, ≈20%	142
	Rifampin	↓ Concentrations	50, 52
	Rifabutin	↓ Concentrations	50
	Ketoconazole	↑ Concentrations	142
	Fluconazole	↑ Concentrations	143
Mycophenolate mofetil	Voriconazole	↑ Concentrations, 7.5×	144
	Posaconazole	↑ Concentrations, 3.8×	144
	Amoxicillin-clavulanate	↓ Concentrations	349, 350
	Ciprofloxacin	↓ Concentrations	349
	Norfloxacin	↓ Concentrations	351
	Metronidazole	↓ Concentrations	351
	Rifampin	↓ Concentrations	51

HSV disease develops in 35% to 68% of transplant recipients not receiving prophylaxis.⁷³ HSV most commonly reactivates during the first month posttransplantation.⁷³ For this reason, it is recommended that all HSV-seropositive transplant recipients receive at least 4 weeks of antiviral prophylaxis after transplantation, usually with acyclovir.⁷⁴ The clinical picture of HSV pneumonitis in posttransplant patients ranges from dyspnea with normal radiographic findings to failure to wean and *acute respiratory distress syndrome* (ARDS). Direct fluorescent antibody testing or real time PCR assay of BAL or other samples provides a rapid diagnosis.⁷⁵ HSV pneumonia should be treated with IV acyclovir, 10 mg/kg every 8 hours, and, if the HSV disease is life-threatening, a reduction in immunosuppression should be considered.^{74,76,77} Foscarnet is recommended for the treatment of acyclovir-resistant HSV, although this is an infrequent problem in transplant patients.⁷⁸

VZV has been reported as a rare and usually late cause of pneumonia in transplant recipients typically presenting with a vesicular rash that precedes respiratory symptoms. IV acyclovir 10 mg/kg IV every 8 hours is the treatment of choice.

Community-acquired respiratory viruses (CARVs) are a common cause of infection after SCT and SOT. CARVs include *respiratory syncytial virus* (RSV), influenza, *metapneumovirus* (MPV) and parainfluenza serotypes 1 and 2, which have their peak primarily in the winter months, and parainfluenza serotype 3 and adenovirus, which are present year round. Risk factors for progression of upper respiratory tract CARV infection to pneumonia in SCT recipients include infection early after transplantation, allogeneic SCT, myeloablative conditioning, GVHD, and lymphopenia.⁷⁹⁻⁸⁴ Risk factors for progression to pneumonia in SOT recipients have not been as well defined; however, the most-immunosuppressed recipients appear to be at greatest risk of severe disease and poor outcome.⁸⁵ CARV infections in transplantation recipients are often characterized by prolonged viral shedding and can be complicated by coinfection with other viral, bacterial, or fungal pathogens.^{84,86-90} In addition to the direct effects, CARV infections can have indirect effects that include an increased risk of acute and chronic rejection such as bronchiolitis obliterans after lung transplantation^{91,92} and concurrent allograft rejection in non-lung SOT recipients.⁹³

Respiratory Syncytial Virus

The incidence of RSV infection after SCT is 1% to 12% with 17% to 70% of infections involving the lower respiratory tract. Mortality rates range from 7% to 33% in the setting of pneumonia.⁷⁹ The incidence of RSV in lung transplant recipients is 5% to 12% with a 10% to 15% mortality rate,^{94,95} while the incidence in liver transplant recipients is 4%.⁹⁶ RSV disease can range from a mild upper respiratory tract infection to life-threatening pneumonia. The most sensitive method for diagnosing RSV infection in symptomatic patients is by *reverse transcriptase* (RT)-PCR assay of nasal wash or BAL.⁹⁷ Ribavirin (orally or IV \pm inhaled ribavirin) is approved for treatment of RSV pneumonitis in SCT recipients^{98,99} and may be combined with IV immunoglobulin or IV palivizumab, a humanized monoclonal antibody against RSV used for prophylaxis. Although there is no controlled study of ribavirin therapy in SOT recipients, inhaled

ribavirin is commonly prescribed for RSV infection in heart and lung transplant recipients.¹⁰⁰⁻¹⁰²

Influenza

The incidence of influenza infection after SCT is 1% to 4%. Mortality rates are 15% to 28% in the setting of influenza pneumonia.⁷⁹ The incidence of influenza in lung transplant recipients is 3% to 14% with progression to lower tract infection in up to 5% of patients.^{94,95,103} Influenza infection is diagnosed in nasal wash, nasopharyngeal swabs, or BAL by rapid antigen detection or RT-PCR methods.¹⁰⁴ Susceptible influenza A strains are treated with the antiviral agents amantadine and rimantadine, and both influenza A and B strains can be treated with zanamivir and oseltamivir.^{93,105} Because oseltamivir-resistant strains of influenza A have been found in transplant patients who continue to shed virus during therapy, these infections may need to be treated with investigational drugs currently in development. Prolonged shedding of influenza virus during treatment of transplant patients also mandates close attention to infection control procedures to prevent spread to staff and other patients.

Parainfluenza and Metapneumovirus

Parainfluenza (PIV), usually serotype 3, is reported to infect 0.2% to 18% of SCT recipients, with lower respiratory tract involvement in 12% to 50% of cases.⁷⁹ The incidence of parainfluenza infection in lung transplant recipients is 2% to 17%.^{94,95} MPV is reported to infect 3% to 7% of SCT recipients (eFig. 91-6) with 27% to 41% of cases involving the lower respiratory tract and has an associated mortality of 33% to 40% for those with pneumonia.⁷⁹ The incidence of MPV infection in lung transplant recipients is 4% to 6%.^{79,94,95} Isolated cases of MPV have also been reported following liver and kidney transplantation.^{95,106,107} MPV infection appears to increase acute allograft rejection.^{95,108} Infection by PIV or MPV is diagnosed by RT-PCR of nasopharyngeal swab, nasal wash, or BAL. Treatment is supportive care; however, IV or inhaled ribavirin and/or IV immunoglobulin has been used to treat lower respiratory tract disease despite the absence of controlled trials.^{95,105,109}

FUNGAL

On the basis of the *Transplant-Associated Infection Surveillance Network* (TRANSNET), the 1-year incidence of *invasive fungal infections* (IFIs) in SOT recipients, in the order of decreasing frequency, is small bowel transplants (11.6%), lung (8.6%), liver (4.7%), heart (4.0%), pancreas (3.4%), and kidney (1.3%).¹¹⁰ The most common pathogens are invasive candidiasis (53%), *invasive aspergillosis* (IA) (19%) (eFigs. 91-7 and 91-8), *Cryptococcus* (8%), non-*Aspergillus* molds (8%) (eFig. 91-9), endemic fungi (5%), and *Zygomycetes* (2%).¹¹⁰ The mortality associated with candidal infections in SOT recipients ranges from 5% to 77% with the highest mortality seen in liver transplant recipients.^{111,112} The mortality rate for IA is related to the type of transplant and ranges from 20% for lung transplants to 66.7% for heart and kidney transplants.^{111,113} Risk factors for IFI in SOT recipients include environmental exposures, the use of high-dose steroids, antilymphocyte therapy, and viral infections, particularly CMV infection.^{114,115} Lung transplant

patients are at particular risk for fungal infections in the anastomotic site.

The incidence of IA infection after SCT (eFig. 91-10, also see Figs. 38-4 and 38-7) ranges from 0.08% to 23% depending on the stem cell source and conditioning regimen.^{113,116} Mortality at 3 months from the time of IA diagnosis ranges from 54% of autologous recipients to 85% for unrelated donor recipients and does not differ for those with early-versus late-onset infections.^{113,116}

Aspergillus infection can present in posttransplantation patients as airway colonization, tracheobronchitis, pulmonary aspergillosis, sinusitis, or disseminated disease.¹¹⁴ Symptoms of invasive pulmonary aspergillosis include dyspnea, fever, productive cough, chest pain, and hemoptysis; however, up to 41% of transplant recipients may have no respiratory symptoms.¹¹⁷ After recovery from neutropenia, 64% of allogeneic SCT recipients with invasive filamentous fungal infection presented with dyspnea, but only 32% were febrile.¹¹⁸

Diagnostic strategies vary. Culture remains the gold standard for the diagnosis of *Candida* infections.¹¹⁹ Similarly, the gold standard for the diagnosis of IA is biopsy with culture in the setting of compatible clinical and radiographic features, although alternative approaches include serologic and molecular testing. For SCT recipients, the serum galactomannan assay has a sensitivity and specificity of 82% and 86%, respectively, for the diagnosis of IA¹²⁰; in contrast, for SOT recipients, the serum galactomannan assay is of uncertain utility, with a sensitivity and specificity of 22% and 84%, respectively.^{120,121} Compared with serum, BAL appears to have higher specificity; galactomannan testing of BAL has a sensitivity of 60% to 82% and a specificity of 95%.¹²²⁻¹²⁴ PCR-based methods for the detection of *Aspergillus* are not yet standardized for clinical use, although published studies indicate that BAL analysis using quantitative RT-PCR has a sensitivity of 67% to 77% and specificity of 90% to 100%.¹²⁴

Treatment of IFI in transplant recipients should be based on the isolated pathogen, hospital-specific susceptibility patterns, and the patient's clinical condition. Gabardi and colleagues¹¹¹ have reviewed potential pathogen-specific treatment options. In general, a two-pronged approach is advised: (1) reduction of the level of immunosuppression to the extent possible and (2) use of an appropriate antifungal agent. It is important to recognize that all clinically relevant azole antimicrobials inhibit cytochrome P450 isoenzyme activity to varying degrees, resulting in increased serum concentrations of cyclosporine,¹²⁵⁻¹³⁰ tacrolimus,^{125,130-135} sirolimus,^{48,136-141} and everolimus¹⁴²⁻¹⁴⁴ that could lead to neurotoxicity and/or nephrotoxicity (see eTable 91-2). Voriconazole is the agent of choice for the treatment of IA based on its superior efficacy and survival benefit in comparison with amphotericin.¹⁴⁵ However, voriconazole is contraindicated in patients receiving sirolimus.¹¹⁴ Liposomal amphotericin B is an alternative in patients who are azole intolerant. Echinocandins (caspofungin, micafungin, anidulafungin) are also an option for the treatment of AI and have low potential for drug interactions, although they may lower tacrolimus levels.¹¹⁴ Surgical resection for invasive pulmonary aspergillosis is a reasonable option in neutropenic patients.¹⁴⁶ Inhaled liposomal amphotericin B can be used for the treatment of *Aspergillus* tracheobronchitis.

Current data support the use of antifungal prophylaxis with either azole antifungal agents or liposomal amphotericin B for SOT recipients.¹⁴⁷ This topic is discussed further in Chapter 38.

Mucormycosis has emerged as an important IFI and accounts for 8% and 2% of IFIs in SCT (see eFigs. 38-8 through 38-12) and SOT (see eFig. 91-9) recipients, respectively, most often as a late complication (>3 months after transplantation) with pulmonary involvement in more than half of cases. The overall mortality rates among SOT recipients are 38% to 48%, while in SCT recipients mortality is at least 75%.¹⁴⁸ First-line therapy is liposomal amphotericin B for at least 6 to 8 weeks and extensive early surgical debridement. A combination of liposomal amphotericin and an echinocandin may be considered in cases that are refractory to first-line therapy.

Pneumocystis jirovecii (previously *Pneumocystis carinii*) remains a potentially life-threatening infection after SCT and SOT, developing in 5% to 15% of recipients in the absence of prophylaxis and having an attributable mortality of 18%.^{39,149} The risk of infection is greatest during the first 6 months after transplantation and decreases significantly after 1 year in all patients except lung transplant recipients.¹⁴⁹ The clinical presentation can include progressive dyspnea, cough, fever, and hypoxemia. Chest radiographs typically show bilateral abnormalities that can include perihilar, interstitial or alveolar opacities, nodules, cystic lesions, or pneumothorax. The diagnosis of PCP is confirmed by the morphologic identification of the *Pneumocystis* organisms in induced sputum, BAL fluid, or tissue.^{149,150} First-line therapy for PCP is high-dose trimethoprim-sulfamethoxazole combined with corticosteroids. Trimethoprim induces cytochrome P450 activity and can lead to decreased serum concentrations of cyclosporine.¹⁵¹ Most transplantation centers use low-dose TMP/SMX for PCP prophylaxis, which is discontinued at 1 year for all groups except lung transplant recipients for whom it is continued indefinitely.¹⁵²

Endemic fungal infections (EFIs) such as blastomycosis (see eFig. 37-15) or histoplasmosis develop in less than 1% of SCT and SOT recipients. The median time from transplant to onset of EFI is 10.5 months (range 2 to 192 months), although 20% of cases are diagnosed 5 or more years after transplantation.^{110,153} The lungs are the most common site of infection, reported in up to 83% of EFI cases; however, the disease can disseminate in more than half of SOT recipients.¹⁵³ In posttransplant patients, disease with blastomycosis or histoplasmosis has an attributable mortality of 25% to 36% and 0% to 11%, respectively.¹⁵³ The incidence of posttransplant coccidioidomycosis in the era of targeted prophylaxis is less than 3%; however, the rates of dissemination and mortality are high at 30% and 29%, respectively.¹⁵⁴⁻¹⁵⁶ *Coccidioides* serology is of uncertain utility in posttransplant recipients due to its low sensitivity.¹⁵⁷

NONINFECTIOUS COMPLICATIONS

Although transplantation recipients are clearly at increased risk for infection, these patients can also

experience noninfectious pulmonary complications. These noninfectious complications can be attributed to pulmonary toxicities of chemoradiation therapy used in preparative regimens or associated with immunosuppressive medications, postoperative surgical complications, allograft rejection or GVHD or as a result of malignancies impacting the lung (see Figs. 91-1 and 91-2). eTable 91-3 describes the most common complications in the immediate postoperative period.

Individual components of some chemotherapy regimens used in SCT are associated with pulmonary toxicity. Carmustine (or *bischloroethylnitrosourea*, BCNU), used as a single agent or in combination before autologous SCT for solid tumor and hematologic malignancies, is associated with acute-onset pneumonitis with an incidence of 4% to 59%.¹⁵⁸⁻¹⁶³ Prior mediastinal radiation therapy, BCNU dose greater than 1000 mg, and age younger than 54 were independent risk factors for developing pneumonitis after autologous SCT for lymphoma.¹⁵⁸ The mechanism of BCNU-associated pulmonary toxicity has not been entirely elucidated but is thought to include oxidative stress, glutathione dysfunction, and immune-mediated lung injury.^{164,165}

Cyclophosphamide is another agent used in combination with total body radiation or other chemotherapy agents in preparative regimens for autologous and allogeneic SCT, which is associated with pulmonary toxicity thought to be related to increased reactive oxygen species generation and depletion of glutathione stores.¹⁶⁶⁻¹⁷⁰ Pulmonary toxicity associated with other chemotherapeutic agents and radiation are discussed elsewhere in this text.

EARLY COMPLICATIONS

Respiratory Failure

Postoperative respiratory failure has been well described in the transplantation literature as an early cause of mortality. After liver transplantation, the incidence of postoperative respiratory failure is reported to be 4% to 42%.^{34,171-174} In a single-center, retrospective study of 212 liver transplant recipients, the causes of postoperative respiratory failure were pneumonia (56%), pulmonary edema (17%), *acute lung injury* (ALI)/ARDS (17%), and neurologic dysfunction (8%).³⁰ In the immediate posttransplantation period, the most common risk factors for noncardiogenic pulmonary edema include reperfusion syndrome, *transfusion-related acute lung injury* (TRALI), sepsis, pneumonia, gastric aspiration, and acute allograft rejection.^{175,176} After kidney and cardiac transplantation, perioperative respiratory failure is less common. In a single-center retrospective study, perioperative respiratory failure was identified in 4% of 178 kidney transplant recipients.¹⁷⁷ Similarly, heart transplantation has a low risk of respiratory failure. In a retrospective single-center study by Lenner and associates,²² 4% of 157 cardiac transplant recipients developed respiratory failure posttransplantation with 71% of episodes in the first 6 months.

After lung transplantation, respiratory failure in the early postoperative period is most commonly the result of infections or *primary graft dysfunction* (PGD). PGD, a form of acute lung injury arising within 72 hours of lung transplantation, is a severe form of ischemia/reperfusion injury

Figure 91-3 Primary graft dysfunction in a lung transplant recipient. A and B, Axial chest CT images (A and B) in a recent lung transplant recipient show extensive right-greater-than-left lower-lobe ground-glass opacity associated with interlobular septal thickening (arrowheads) and dense consolidation. These imaging findings are not specific but are consistent with acute lung injury. Small bilateral pneumothoraces (*) are consistent with the recent bilateral lung transplantation. (Courtesy Michael Gotway, MD.)

(Fig. 91-3). The incidence is 10% to 30% of all lung transplant recipients.¹⁷⁸⁻¹⁸² Treatment is primarily supportive care including low-stretch ventilation strategies and avoidance of excessive fluid administration.¹⁸³ (A more detailed discussion of PGD is presented in Chapter 106).

For SCT patients, a spectrum of noninfectious pulmonary complications can develop in the early posttransplantation period that falls under the category of the *idiopathic pneumonia syndrome* (IPS). IPS is broadly defined as widespread alveolar injury seen after SCT in the absence of active lower respiratory tract infection, cardiac dysfunction, acute renal failure, or iatrogenic fluid overload (eFig. 91-11).^{184,185} IPS encompasses a spectrum of clinical presentations thought to result from a variety of lung insults including toxic effects of the SCT conditioning regimen, immunologic cell-mediated injury, inflammatory cytokines, and occult pulmonary infections.^{184,186-193}

The cumulative incidence of IPS after *allogeneic* SCT ranges from 2.2% following nonmyeloablative conditioning

e-Table 91-3 Most Common Noninfectious Complications in the Immediate Postoperative Period for Solid Organ Transplant Recipients

Transplantation	Noninfectious Postoperative Complications
Liver	Pulmonary edema/Acute respiratory distress syndrome Diaphragmatic dysfunction Pleural effusions
Lung/Heart-lung	Reperfusion pulmonary edema Primary graft dysfunction Bronchial anastomosis dehiscence Acute hyperinflation of native lung Diaphragmatic dysfunction
Heart	Diaphragmatic dysfunction Mediastinitis Pulmonary edema Pleural effusions
Kidney	Pulmonary edema Venous thromboembolic disease

to 8.4% following conventional, full-intensity radiation containing preparative regimens.¹⁹⁴ The median time of onset after allogeneic SCT is 19 days (range, 4 to 106 days) with mortality rates ranging from 60% to 80% overall to greater than 95% for patients requiring mechanical ventilation.^{184,185,194-196} Although IPS also develops after *autologous* SCT, the incidence is lower, the median time to onset is generally later (63 days; range 7 to 336 days), the response to corticosteroids is usually prompt and the prognosis is favorable compared with IPS in allogeneic SCT recipients.^{40,197-202} Risk factors for IPS after allogeneic SCT include full-intensity conditioning with total body irradiation, acute GVHD, older recipient age, and an underlying diagnosis of acute leukemia or myelodysplastic syndrome.^{185,194,197,197a} Risk factors for IPS following autologous SCT include older patient age, severe oral mucositis, conditioning regimens using total body irradiation or BCNU, chest irradiation within 2 weeks before transplant, female gender, and an underlying diagnosis of solid tumor.¹⁹⁸⁻²⁰¹

Current standard treatment strategies of IPS include broad-spectrum antibiotics and IV corticosteroids and supportive care with lung protective mechanical ventilation and venovenous ultrafiltration for those with respiratory failure. Response to corticosteroids (≤ 2 mg/kg/day) has shown mixed efficacy in allogeneic SCT recipients, which likely reflects the diversity of underlying causes responsible for the lung insult. Compared with lower doses, higher doses of corticosteroid therapy (>2 mg/kg/day) have not been shown to improve outcome but are associated with increased complications including fungal infection.^{194,203} Prophylaxis against filamentous fungal infection with voriconazole or micafungin is recommended during treatment with corticosteroids (≥ 0.5 mg/kg/day) because fungal pneumonia was identified in 16% (4/25) of IPS patients at the time of autopsy in a single-center study.²⁰⁴

Preclinical and clinical studies suggest that neutralization of *tumor necrosis factor* (TNF)- α may be a useful thera-

peutic strategy for IPS. In a single-center study, etanercept (0.4 mg/kg administered subcutaneously twice weekly for 4 weeks) in conjunction with systemic corticosteroids and empiric antibiotics was associated with significant clinical improvement in 66% (10/15) of IPS patients.²⁰⁵ In a multicenter, Phase II single-arm, open-label study by Yanik and colleagues²⁰⁶ in pediatric SCT recipients, treatment with etanercept (0.4 mg/kg/dose twice weekly for 8 doses) plus corticosteroids (2 mg/kg/day) resulted in a complete response in 71% (20 of 28) of patients and was associated with a high overall survival compared with historical controls.¹⁸⁵

As a clinical spectrum, IPS encompasses several descriptive forms of lung dysfunction.^{184,185} One such subset is termed *diffuse alveolar hemorrhage* (DAH), also called *acute pulmonary hemorrhage* (Fig. 91-4 and Video 91-1) or *hemorrhagic alveolitis*. DAH generally develops in the immediate posttransplant period and is characterized by progressive dyspnea, cough, and hypoxemia with or without fever. The cumulative incidence of DAH is 5% to 12% of SCT patients with a median time of onset of 19 days (range, 5 to 34 days) in allogeneic recipients and 12 days (range, 0 to 40 days) in autologous patients.^{198,207-211} The diagnosis of DAH is based on progressively bloodier return of BAL fluid (see Fig. 67-3).¹⁹⁸ Treatment of DAH consists of aggressive platelet support to maintain a platelet count greater than or equal to 100,000 and high-dose systemic corticosteroids (2 mg/kg/day to 1 g/m²/day).²¹² The addition of aminocaproic acid or recombinant factor VII may further improve outcomes.^{209,213-215} Despite these interventions, the mortality from DAH ranges from 60% to 100% with death usually due to multiorgan failure within 3 weeks of diagnosis.^{208,209,216}

Peri-engraftment respiratory distress syndrome (PERDS) is another clinical subset of IPS. PERDS by definition develops within 5 days of engraftment and accounts for 33% of IPS cases after allogeneic SCT (eFig. 91-12 and Video 91-2).²¹⁷

Figure 91-4 Diffuse alveolar hemorrhage following stem cell transplantation. A, Frontal chest radiograph performed in a patient 17 days following stem cell transplant shows multifocal bronchovascular thickening and consolidation. B–E, Axial chest CT at the level of the aortic arch (B), carina (C), right middle lobe bronchus (D), and lung bases (E) displayed in lung windows shows multifocal ground-glass opacity with areas of consolidation (arrows, B and C) shown to represent diffuse alveolar hemorrhage. Numerous centrilobular nodules (arrowheads, D and E), commonly seen in patients with pulmonary hemorrhage, are present. (See Video 91-1 for the CT scan.) (Courtesy Michael Gotway, MD.)

Although the clinical presentation of PERDS after SCT is similar to other subsets of IPS, lung dysfunction is more responsive to corticosteroids and the prognosis is better.²¹⁸⁻²²⁰

Delayed pulmonary toxicity syndrome (DPTS) also falls within the spectrum of IPS.²²¹ The incidence of DPTS is 29% to 64% in autologous SCT recipients (eFig. 91-13) receiving chemotherapy with regimens containing BCNU, cyclophosphamide, and cisplatin. The median time of onset is 45 days (range, 21 to 149 days), and treatment with corticosteroids (1 mg/kg/day) results in resolution in up to 92% of cases.²²¹⁻²²³

Venous Thromboembolic Disease

Venous thromboembolism (VTE) is an under-recognized complication of SOT, especially in lung transplant recipients. In an autopsy series, pulmonary embolism was diagnosed in 34 (27%) of 126 lung and heart-lung transplant recipients.²²⁴ By comparison, pulmonary embolism is diagnosed in 5% to 7% of lung transplant recipients antemortem, suggesting underdiagnosis of this complication.²²⁵ In renal transplant patients, the incidence of VTE ranges from 0.6% to 25%²²⁶⁻²²⁸ and is associated with advanced renal insufficiency, acute CMV infection, and cyclosporine use,²²⁹⁻²³¹ whereas in liver transplant patients, the incidence of pulmonary embolism was 1% overall.^{232,233} In a cohort of 159 heart recipients from a single center, only 2 patients developed VTE.²²

SCT patients are at increased risk of developing VTE. In a retrospective study of 1514 SCT recipients, the incidence of symptomatic VTE within the first 180 days post-transplantation was 4.6% including a 0.7% incidence of non-catheter-associated lower extremity DVT and 0.6% incidence of pulmonary embolism.²³⁴ This result is comparable with a smaller, retrospective study of 589 SCT patients.²³⁵ The median time after SCT admission to the development of non-catheter-associated lower extremity DVT was 63 days and for pulmonary embolism, 66 days.²³⁴ Independent risk factors for the development of VTE were prior VTE and GVHD.^{234,236} Importantly, thrombocytopenia was only partially protective against the development of VTE.²³⁴ The safety and efficacy of thromboprophylaxis in SCT patients remains uncertain, and anticoagulant therapy for documented VTE should be accompanied by platelet transfusions to maintain a platelet count of $50 \times 10^9/L$ or greater to reduce the risk of bleeding complications.

Diaphragmatic Dysfunction

Diaphragmatic dysfunction can develop due to injury to the phrenic nerve, perhaps from hypothermia or mechanical damage during surgery. The incidence of diaphragmatic dysfunction after heart or heart-lung transplantation has been reported from 12% to 43% and after lung transplantation from 7% to 30%.²³⁷⁻²³⁹ The reported incidence of diaphragmatic paralysis among liver transplant recipients ranges from 38% to 44% and is attributed to right phrenic nerve crush injury at the time of suprahepatic vena cava clamping.^{240,241} Diaphragmatic dysfunction has been associated with a significantly increased number of ventilator days and ICU length of stay for liver, heart-lung, and lung-only transplant recipients compared with recipients without phrenic nerve damage.^{239,240,242}

LATE COMPLICATIONS

Drug-Induced Pulmonary Toxicity

A spectrum of drug-induced lung diseases has been reported after transplantation in association with immunosuppressive therapies. Implicated immunosuppressive agents and their patterns of pulmonary toxicity are listed in eTable 91-4.

Monoclonal antibodies used as induction immunosuppressive therapy after SOT are infrequently associated with pulmonary toxicity. Infusion of muromonab-CD3 (OKT3) can produce a cytokine release syndrome thought to be from a transient activation of T cells before they undergo cell lysis.²⁴³ The clinical manifestations of this syndrome are fever, chills, headache, dyspnea, myalgia, and hypotension and can result in pulmonary edema and intra-allograft thrombosis.^{244,245} Basiliximab is linked to severe noncardiogenic pulmonary edema within 48 hours of infusion.^{246,247} Alemtuzumab is associated with DAH.²⁴⁸ The off-label use of rituximab, as part of the induction immunosuppressive regimen for renal transplantation, has also been reported to result in a cytokine release syndrome, with ARDS and DAH developing within hours of administration.^{244,249} Additional patterns of rituximab-induced lung injury include interstitial pneumonitis and cryptogenic organizing pneumonia, which can develop within weeks of administration and in most cases completely resolve after discontinuation of therapy with or without corticosteroids.²⁵⁰⁻²⁵⁴

IV and oral cyclosporine given after liver, kidney, and bone marrow transplantation has been reported to cause a noncardiogenic pulmonary edema and ARDS that resolves when the medication is discontinued. The reaction is postulated to be idiosyncratic.²⁵⁵⁻²⁵⁹

The *mammalian target of rapamycin* (mTOR) inhibitors, sirolimus and everolimus, bind to rapamycin-FK-binding protein-12 to inhibit T and B lymphocyte proliferation for induction and long-term maintenance of immunosuppression. Pulmonary toxicity has been reported in up to 11% of SOT recipients receiving sirolimus.^{260,261} Pulmonary toxicity developed within 6 months of the initiation of sirolimus therapy in 47% of cases and within 12 months in 65% of recipients.²⁶² The clinical presentation includes cough (96%), fatigue (83%), fever (67%), dyspnea (33%), and hemoptysis (8%). Physical examination is notable for hypoxemia (50%) and inspiratory crackles (50%).²⁶⁰ Radiographic findings on CT scan include patchy bilateral asymmetrical peripheral consolidations (organizing pneumonia-like pattern) (79%), reticular and ground-glass opacities (17%), and lobar consolidation (4%).²⁶⁰ BAL is reported to show lymphocytic or eosinophilic alveolitis in up to 92% of cases.^{260,263,264} The predominant histologic patterns are organizing pneumonia, pulmonary hemorrhage, diffuse alveolar damage, and, in a minority of cases, pulmonary alveolar proteinosis.^{265,266} Drug discontinuation with or without corticosteroids (1 mg/kg/day) is the mainstay of treatment, with complete resolution of symptoms within 2 to 4 months.^{260,261,263,265} Less severe cases can be managed by a reduction in the sirolimus dose with close monitoring of serum levels; however, relapses have been reported with this approach.²⁶¹ Sirolimus is also thought to be a potent antifibroproliferative agent and has been associated with severe wound healing complications leading to a

e-Table 91-4 Pulmonary Toxicity of Immunosuppressant Agents

Immunosuppressant	Pulmonary Toxicity
MONOCLONAL ANTIBODIES	
Muromonab-CD3 (OKT3)	Capillary leak (noncardiogenic pulmonary edema), ARDS
Basiliximab-CD25 (anti-IL-2 receptor) antibody	Capillary leak (noncardiogenic pulmonary edema)
Alemtuzumab anti-CD52 antibody	Diffuse alveolar hemorrhage
Rituximab anti-CD20 antibody	ARDS, diffuse alveolar hemorrhage, interstitial pneumonitis, cryptogenic organizing pneumonia, pulmonary fibrosis, hypersensitivity pneumonitis
CALCINEURIN INHIBITORS	
Cyclosporine	Capillary leak (noncardiogenic pulmonary edema), ARDS
Tacrolimus	Cryptogenic organizing pneumonia
mTOR INHIBITORS	
Sirolimus	Organizing pneumonia, diffuse alveolar hemorrhage, ARDS, pulmonary alveolar proteinosis
Everolimus	Interstitial pneumonitis, diffuse alveolar hemorrhage, ARDS
Mycophenolate mofetil	Pulmonary edema, ARDS, pulmonary fibrosis, bronchiectasis
Azathioprine	Cryptogenic organizing pneumonia, diffuse alveolar hemorrhage, interstitial pneumonitis, laryngeal edema, vasculitis

ARDS, acute respiratory distress syndrome.

high rate of bronchial anastomosis dehiscence after lung transplantation.^{267,268} As a consequence, sirolimus administration is not started until 3 months after transplantation or after bronchial wound healing is complete.^{268,269}

Everolimus, a derivative of sirolimus, is associated with pulmonary toxicity in 3.3% of heart transplant recipients with clinical, radiographic, and histologic features similar to those reported with sirolimus.²⁷⁰⁻²⁷³

Obliterative Bronchiolitis and Cryptogenic Organizing Pneumonia

In allogeneic SCT recipients, late-onset noninfectious pulmonary complications have been reported in 13% to 26%.^{274,275} Obliterative bronchiolitis, also called *bronchiolitis obliterans syndrome* (BOS), and *cryptogenic organizing pneumonia* (COP), formerly called *bronchiolitis obliterans organizing pneumonia* (BOOP), are two late-onset noninfectious pulmonary complications of allogeneic SCT strongly associated with GVHD.²⁷⁶⁻²⁸⁰ The clinical hallmark of BOS is the development of new-onset, fixed airflow obstruction that is pathologically characterized by progressive circumferential fibrosis of the terminal bronchioles.²⁸¹

Historically, the incidence of BOS after SCT has ranged from 2% to 26%, depending on the definition of airflow obstruction used in the study.^{277,282} In an attempt to standardize the definition of BOS after SCT for clinical and research purposes, the National Institutes of Health Chronic GVHD consensus project published in 2005 diagnostic criteria, which define BOS by five characteristics: (1) *forced expiratory volume in 1 second* (FEV₁) less than 75% predicted; (2) FEV₁/forced vital capacity (FVC) ratio less than 0.7; (3) evidence of air trapping, small airway thickening, or bronchiectasis on high-resolution computed tomography (eFig. 91-14) or *residual volume* (RV) greater than 120% predicted or pathologic confirmation of constrictive bronchiolitis; (4) absence of respiratory tract infection; and (5) clinical manifestation of chronic GVHD in at least one other organ.²⁸³ Using the consensus diagnostic criteria in a single-center, retrospective study of 1145 allogeneic SCT recipients, Au and colleagues²⁸¹ reported the overall prevalence of BOS to be 5.5% among all transplanted patients and 14% among patients with chronic GVHD. In this study, the median time from transplant to diagnosis of BOS was 439 days (range, 274 to 1690 days). BOS conferred a 1.6-fold increased risk for death after diagnosis.²⁸¹ Multivariate analysis of this same cohort of SCT recipients identified chronic GVHD and lower IgG levels (<350 ng/dL) as independent risk factors for the development of BOS.²⁸¹

The onset of BOS is usually insidious, with nonproductive cough (60% to 100%), dyspnea (50% to 70%), and wheezing (40%).²⁸⁴ Although histologic evaluation of lung tissue is considered the gold standard for the diagnosis of bronchiolitis obliterans, the utility of transbronchial biopsies is limited by low sensitivity (≈20% to 50%) attributed to the heterogeneity of the lesions and small biopsy size.²⁸⁵⁻²⁸⁷ In general, more invasive procedures such as open-lung biopsy or *video-assisted thorascopic* (VATS) procedures are reserved for unusual presentations. In most instances, the diagnosis of BOS is based on the presence of persistent expiratory airflow obstruction on spirometry in the absence of other causes such as asthma, tobacco-related emphysema, or lower respiratory tract infection.²⁸⁴

Although the etiology of BOS remains uncertain, the suspected cause is immune-mediated injury of lung epithelium due to allorecognition of lung antigens.^{277,288}

There are no prospective studies of the treatment of airflow obstruction after SCT. Given the presumed alloimmune pathogenesis of BOS, immunosuppressive therapy remains the foundation of treatment. The historic clinical approach to BOS treatment has been with high-dose systemic corticosteroids for extended periods of time such as 12 to 24 months. However, given the limited response to treatment and substantial morbidities associated with high-dose systemic corticosteroid therapy, adjunctive approaches have been tried, including the use of inhaled corticosteroids,^{288,289} azithromycin,²⁹⁰ and montelukast, a leukotriene inhibitor,^{291,292} which have shown some efficacy in small clinical trials of BOS after SCT. Other emerging therapies for BOS include extracorporeal photophoresis,²⁹³⁻²⁹⁶ TNF- α blockade with infliximab,²⁹⁷ imatinib,²⁹⁸ and statins.²⁹⁹ Despite aggressive treatment, BOS after SCT has a poor prognosis with an overall survival rate of 44% at 2 years and 13% at 5 years.^{278,300-303,303a}

After lung transplantation, the BOS that develops has similar clinical manifestations and histologic characteristics as the BOS of allogeneic SCT recipients. However, BOS is much more common after lung transplantation, developing in 50% of lung transplant recipients at 5.6 years post-transplantation (see Fig. 106-5).²⁸⁵ A detailed discussion on obliterative bronchiolitis syndrome after lung transplantation is available in Chapter 106.

After SCT, COP is an infrequent, late-onset noninfectious complication. In a single-center, retrospective case-control study, Freudenberger and colleagues³⁰⁴ identified 49 cases (0.9%) of biopsy-proven COP among 5340 allogeneic patients. In a smaller, retrospective study COP was diagnosed in 12 (2%) of 603 allogeneic SCT recipients.³⁰⁵ The median time to diagnosis following SCT is reported to be 108 days (range 5 to 2819 days).³⁰⁴ Patients commonly present with fever (61%), dyspnea (45%), and nonproductive cough (43%) with a median symptom duration of 13 days (range 3 to 65 days). Pipavath and associates³⁰⁶ reported the imaging features of biopsy-proven COP in a cohort of 16 allogeneic SCT recipients. The CT findings included ground-glass opacities (94%), consolidation (50%) (Fig. 91-5), and linear opacities (50%) with an upper lobe predominance (63%). The pulmonary physiologic changes associated with a diagnosis of COP were predominantly new restrictive (43%) and diffusing capacity abnormalities (64%) and, to a lesser extent, a new obstructive pattern (11%).^{304,305}

Bronchoscopy and BAL are recommended to rule out lower respiratory tract infection and to establish the diagnosis of COP. BAL is characterized by lymphocytosis (>20% lymphocytes) with a decreased CD4/CD8 ratio.³⁰⁵ Unlike bronchiolitis obliterans, COP can usually be diagnosed by bronchoscopic biopsy, although VATS may be required in cases presenting with atypical features.^{305,307,308} The histologic characteristics included (1) patchy filling of respiratory bronchioles, alveolar ducts, and peribronchiolar sacs with polypoid masses of granulation tissue; (2) widening of alveolar septa and infiltration by mononuclear cells; and (3) accumulation of foamy macrophages within alveoli (see Figs. 63-34 and 63-35).³⁰⁴ There is an association between

Figure 91-5 Graft-versus-host disease in an allogeneic stem cell transplant recipient presenting as organizing pneumonia. **A** and **B**, Axial chest CT shows patchy upper lobe consolidation (arrowhead, **A**) and right lower lobe nodules (double arrowheads, **B**). **C** and **D**, Several weeks following **A**, repeat chest CT shows progression of the abnormalities seen previously. The peripheral, peribronchial nature of the consolidation is particularly evident in the right lower lobe (arrows, **D**). **E** and **F**, Follow-up chest CT 1 month following **B** shows continued progression in upper (arrowhead) and lower (arrow) consolidation. Biopsy subsequently showed organizing pneumonia. (Courtesy Michael Gotway, MD.)

acute and chronic GVHD and subsequent development of COP.³⁰⁴ Patients with COP were more likely to have acute GVHD involving the skin and chronic GVHD involving the gut and oral cavity, suggesting that the pathogenesis is, at least in part, related to alloreactive lung injury.

Corticosteroid therapy is the standard treatment for COP after SCT, although doses and duration have been empirically derived. Historically, prednisone doses of 0.75 to 1.5 mg/kg/day were prescribed with a progressive decrease for a total duration of 24 weeks.^{309,310} However, in order to limit the risk of iatrogenic complications, current recommendations are to start with prednisone at 0.75 mg/kg/day for 4 weeks and taper over a total of 12 weeks, possibly in conjunction with use of a macrolide.³¹¹⁻³¹³ The prognosis of COP in SCT recipients is generally favorable with resolution in 57%, stable disease in 21%, and progressive COP in 22% despite corticosteroids with 16% of patients dying from respiratory failure.³⁰⁴ Up to 75% of patients relapse during the corticosteroid taper or after stopping treatment and typically respond to reinitiation or increased dosing of corticosteroid therapy.^{305,311}

Pulmonary veno-occlusive disease (PVOD) is a rare, late-onset complication after SCT that presents with the insidious onset of fatigue and exertional dyspnea within 3 to 4 months after transplant.³¹⁴⁻³¹⁹ The physical examination typically shows hypoxemia and resting tachycardia consistent with pulmonary hypertension. Right heart catheterization demonstrates elevated pulmonary artery pressures with normal pulmonary capillary wedge pressure, and angiography is used to exclude pulmonary emboli as the etiology for the pulmonary hypertension. The diagnosis of PVOD is strongly supported by the triad of pulmonary artery hypertension, radiographic evidence of pulmonary

edema, and normal pulmonary artery occlusion pressures; however, lung biopsy confirms the diagnosis by the presence of extensive and diffuse intimal proliferation and fibrosis of pulmonary venules.³²⁰ Treatment consists of high-dose corticosteroids (methylprednisolone 2 mg/kg/day) with anecdotal success, but the overall prognosis of PVOD after SCT remains poor.³¹⁶

Pulmonary cytolytic thrombus (PCT) is another noninfectious pulmonary complication that involves the pulmonary vasculature, seen exclusively in allogeneic SCT recipients and almost always in children. The incidence of PCT has been reported to range from 1.2% to 4%^{321,322} with a median onset at 3 months (range 1.3 to 11.3 months) after transplant.³²² The clinical manifestations include fever, cough, and respiratory distress, and CT findings range from small, peripheral nodules to diffuse opacities.^{321,323-325} Diagnosis requires lung biopsy that is characterized by vascular occlusions in distal pulmonary vessels, entrapment of leukocytes, endothelial disruption, and infarction of adjacent tissue.³²¹ In a single-center, retrospective study, grades II to IV acute and chronic GVHD were independent risk factors for developing PCT.³²² Treatment for PCT consists of systemic corticosteroids (prednisone 1 to 2 mg/kg/day) until pulmonary symptoms resolve (typically within 2 weeks) followed by a steroid taper over 2 to 4 weeks.³²² The strong association with acute and chronic GVHD, as well as the response to corticosteroid therapy, suggest that PCT is an alloreactive lung injury. The prognosis with PCT is favorable, and there have been no reported deaths attributable to this entity.^{322,326}

Pulmonary Metastatic Calcifications

Pulmonary metastatic calcification is a well-known complication of chronic renal failure and a rare complication in

renal transplant recipients.^{327,328} The lesions are typically nodular opacities of 2 to 12 mm in diameter that may be unilateral or diffuse with a predilection for the upper lobes (eFig. 91-15).³²⁸ Patients can be asymptomatic, although progression of the lesions may lead to dyspnea along with a restrictive pattern and diffusing capacity abnormality on pulmonary function testing.³²⁸ The clinical significance of pulmonary metastatic calcification is distinguishing this entity from pulmonary infections or malignancy in the transplant recipient.

Malignancy

Organ transplantation is associated with an increased risk of developing malignancies. Risk factors for malignancy include prolonged use of immunosuppressive therapy, infection with oncogenic viruses, progressive aging of transplant recipients, longer survival after transplantation and, less commonly, malignant cells transmitted in the donor tissue.³²⁹⁻³³¹ Transplant-related malignancies affecting the lung include non-Hodgkin lymphoma, bronchogenic carcinoma, posttransplantation lymphoproliferative disorder, and *Kaposi sarcoma* (KS). In a large, population-based, registry linkage study of 175,732 SOT recipients, the incidence of non-Hodgkin lymphoma was 7.54-fold higher in transplant recipients compared with the general population.³³⁰ Likewise, the incidence of lung cancer was increased 6.13-fold in lung, 2.67-fold in heart, 1.95-fold in liver, and 1.46-fold in kidney transplant recipients compared with the general population.³³⁰ For further discussion of lung cancer in lung transplant recipients, see Chapter 106.

Posttransplantation lymphoproliferative disorder (PTLD) is an infrequent but serious complication composed of a heterogeneous group of altered B-cell monoclonal and polyclonal proliferation disorders that can develop in association with immunosuppressive therapy. After SOT, the incidence of PTLD in adults varies among studies but is generally higher in lung (4.2% to 10.0%), heart-lung (2.2% to 5.8%) and heart (1% to 6.3%) compared with liver (1% to 2.8%) and kidney (1% to 2.3%) (eFig. 91-16) recipients.^{332,333-335} The incidence appears to have a bimodal distribution after lung transplantation with 25% to 47% of cases developing within the first 12 months of transplantation.^{333,335} Risk factors for the development of PTLD after SOT include age at the time of transplantation, degree of immunosuppression, use of OKT3 or antilymphocyte globulin, number of episodes of acute rejection, seronegativity to EBV before transplantation (especially with an EBV-seropositive donor) and CMV or hepatitis C infection.^{336,337}

After allogeneic SCT, PTLD is a rare but serious complication as well (eFig. 91-17). In a multicenter study of 18,014 allogeneic SCT recipients, the overall incidence of PTLD was 1% with 82% of cases diagnosed within the first year posttransplantation.³³⁸ For early-onset PTLD after SCT, risk factors included unrelated or HLA mismatched related donor stem cell source, T-cell depletion of the donor marrow, and use of antithymocyte globulin or anti-CD3 monoclonal antibody for prophylaxis or treatment of acute GVHD. For late-onset PTLD, the only risk factor identified was chronic extensive GVHD. The incidence of PTLD increased to 8% for patients with two risk factors and to 22% for those with three or more risk factors. Pulmonary involvement with

PTLD after allogeneic SCT has been reported in 18% of cases.³³⁹ Overall long-term survival was lower for SCT recipients (35%) compared with SOT recipients (55%) and was the worst for patients transplanted for hematologic malignancies.³³⁹ Additional information on PTLD is presented in Chapter 106.

KS is a soft tissue malignancy associated with immunosuppression in SOT recipients. In a large population-based study, among 234,127 recipients, the incidence of KS was 8.8 per 100,000 person-years with the median time from transplantation to KS of 1.5 years.³⁴⁰ Risk factors for the development of KS posttransplantation in the United States included male gender, older recipient age, Hispanic ethnicity, non-U.S. citizenship, and number of mismatches at the HLA-B locus.³⁴⁰ KS develops primarily in transplant recipients with preexisting human herpesvirus-8 infection.³⁴¹⁻³⁴³ Twenty percent of KS cases after organ transplantation have visceral involvement including the lungs.³⁴⁰

Key Points

- Pulmonary complications are common following stem cell and solid organ transplantation, and their incidence follows a characteristic pattern.
- Risk factors for the development of pulmonary complications are varied and include the type of organ or tissue transplanted, degree and duration of immunosuppression, preexisting lung disease, concomitant medication administration, perioperative insults, and environmental exposures.
- Infectious etiologies must be aggressively assessed, often requiring invasive lung sampling for accurate diagnosis, and then promptly treated.
- The use of antimicrobial prophylaxis for commonly encountered pathogens has reduced the incidence of certain pulmonary infections in transplant recipients. However, antimicrobial prophylaxis has also led to the emergence of resistant pathogens.
- Noninfectious complications after transplant can be seen early, including acute respiratory distress syndrome, idiopathic pneumonia syndrome, venous thromboembolic disease, and diaphragmatic dysfunction, or late, including drug-induced toxicity, bronchiolitis obliterans syndrome, and posttransplantation lymphoproliferative disorder.

PULMONARY COMPLICATIONS OF PRIMARY IMMUNODEFICIENCIES

JOHN M. ROUTES, MD

INTRODUCTION

DIAGNOSTIC WORKUP

Antibody Deficiencies
Cellular Immunodeficiency
Complement Deficiencies
Phagocyte Deficiencies

DEFICIENCY IN BOTH CELLULAR IMMUNITY AND ANTIBODY PRODUCTION

Severe Combined Immunodeficiency

ANTIBODY DEFICIENCIES

Immunoglobulin A Deficiency
X-Linked Agammaglobulinemia

Common Variable Immunodeficiency

Specific Antibody Deficiency

Immunoglobulin G Subclass Deficiency

X-Linked Lymphoproliferative Syndrome

Hyper-Immunoglobulin M Syndrome

X-Linked Hyper-IGM Syndrome

COMBINED IMMUNODEFICIENCIES OR SYNDROMIC IMMUNODEFICIENCIES

GATA-2 Deficiency

DiGeorge Syndrome

Wiskott-Aldrich Syndrome

Ataxia-Telangiectasia

Hyper-Immunoglobulin E Syndrome

PHAGOCYTIC CELL DISORDERS

Phagocytic Defects: Increased Apoptosis of Neutrophils

Decreased Adherence/Chemotaxis

Disorders of Leukocyte Signaling

DISORDERS IN INNATE IMMUNITY

MyD88 and IRAK-4 DEFICIENCIES

Complement Deficiencies

INTRODUCTION

Primary immune deficiency disorders (PIDDs) are disorders of the immune system that predispose individuals to infection and frequently malignancy and autoimmunity as well.¹ Most PIDDs are inherited disorders. However, in some PIDDs, such as *common variable immunodeficiency* (CVID), a family history is often lacking and a genetic cause has yet to be found. Furthermore, in some diseases, somatic mutations, not germline mutations, cause the particular disorders.² Thus, we should not limit the diagnosis of PIDD to disorders that are inherited.

Many incorrectly believe that PIDDs are rare and are diagnosed almost exclusively in children. The frequency of clinically important PIDDs is approximately 1 in 2000 individuals.³ The majority of people affected with PIDD are now adults, not children.⁴ Among the patients in the United States receiving *intravenous immune globulin* (IVIG), 23% are ages 30 to 44 years and 34% are in the 45- to 65-year age group. The increasing age of patients with PIDD is due in part to improvements in recognition, diagnosis, and treatment with a concomitant increase in survival rates.

A diagnostic evaluation for PIDD is a fundamental but often-overlooked issue in the evaluation of patients with pulmonary infections. Numerous studies indicate the importance of the early diagnosis of PIDD in reducing the morbidity and mortality associated with recurrent infections. For example, early *hematopoietic stem cell transplantation* (HSCT) (<3.5 months of age) results in dramatically improved outcome in infants with *severe combined immunodeficiency* (SCID).² Treatment with high-dose IVIG can prevent many of the infectious sequelae in patients with primary antibody deficiency states.⁵ Many routine childhood vaccines use attenuated, live organisms. Because the use of such vaccines may lead to disseminated infections in patients with antibody or cellular immunodeficiencies, these vaccines are contraindicated. Thus, the early diagno-

sis of PIDD can prevent these life-threatening infections, further supporting the contention that early detection leads to improved outcomes.

The decision to evaluate patients with pulmonary infection for primary immunodeficiencies cannot be made in the context of the pulmonary infection alone; several additional factors need to be considered (Table 92-1). In general, an evaluation of the immune system is warranted in patients with two or more radiographically documented pneumonias. However, a single infection of the lung with an opportunistic pathogen warrants an evaluation to exclude both primary and secondary immunodeficiencies. A patient with first pneumonia, but with a history of intractable sinus disease or recurrent gastrointestinal infection or with other disorders found more frequently in patients with PIDD (e.g., autoimmunity, intractable eczema, unusual facies), should also be evaluated for a PIDD. Approximately 20% of patients with CVID are diagnosed at 50 years of age or later. Therefore, older age should not be used to exclude the diagnosis of a PIDD.

Several clues in the history and clinical presentation of patients with primary immunodeficiencies suggest the type of immunologic defect present (Table 92-2). The onset of diseases associated with cellular immunodeficiencies usually begins in early infancy. Infections may be seen with opportunistic or unusual pathogens or mycobacteria; there may be disseminated viral infections or severe oral candidiasis. Diarrhea and malabsorption are common, and growth is delayed. In contrast, the onset of infections in patients with antibody deficiencies, such as *X-linked agammaglobulinemia* (XLA), is usually delayed until after 6 months, when maternal antibodies are no longer present. Recurrent and severe upper and lower respiratory tract infections are the usual mode of presentation. Complement deficiencies may present in a manner similar to antibody deficiencies or with recurrent *Neisseria* spp. infections. In contrast to patients with cellular immunodeficiencies,

growth is usually not delayed in patients with complement or antibody deficiencies.

One common misconception is that opportunistic pathogens are overwhelmingly the cause of most infections in patients with primary immunodeficiencies. In fact, many infections in immunodeficient patients are with pathogens that are common in the community; however, in patients with PID, these infections may be of unusual severity and respond poorly to therapy. For example, recurrent infections with *Streptococcus pneumoniae* are frequent in patients with several types of PID, such as antibody deficiencies; com-

plement deficiencies; Toll-like receptor signaling deficiencies (MyD88, IRAK-4); and mutations in nuclear factor- κ B essential modulator.⁶ Finally, although this section deals exclusively with PIDs, it is essential to exclude secondary immunodeficiencies or other medical conditions (e.g., lymphoproliferative disorders and malignancy, malnutrition, immunosuppressive drugs, protein-losing states, kidney failure, liver failure, heart failure, sickle cell anemia) that predispose patients to recurrent infection.

DIAGNOSTIC WORKUP

A number of readily available and inexpensive screening tests should be used in the evaluation of a patient with a possible immunodeficiency (Table 92-3).⁷ In an adult, CVID would be the most likely diagnosis, and phagocytic defects and combined immunodeficiencies only rarely present; thus, for adult patients, the following algorithm can be used for screening (Fig. 92-1). Abnormalities found in these screening tests indicate the need for additional sophisticated studies in collaboration with a clinical immunologist. The goal in the evaluation of immunodeficient patients should be to define the specific genetic abnormality whenever possible.

Table 92-1 General Criteria that May Warrant an Immunologic Evaluation

Chronic infections
Recurrent infections
Opportunistic or unusual pathogens
Unusual sites of infections
Incomplete clearing of infection
Poor response to antimicrobial therapy
Associated conditions (unusual facies, tetany, failure to thrive, intractable diarrhea, thrush, intractable eczema, autoimmunity)

Table 92-2 Examples of Primary Immunodeficiencies

Type of Immunodeficiency	Example	Mode of Presentation
Antibody	XLA, CVID	Upper and lower respiratory tract infections (encapsulated and atypical bacteria), giardiasis
T cell	DiGeorge syndrome	Abnormal facies, lymphopenia, thrush, recurrent sinopulmonary infections
Combined B cell and T cell	SCID (multiple causes)	Opportunistic infections, thrush, intractable diarrhea, failure to thrive
Cellular/complex	IFN- γ /IL-12/IL-23 axis	Atypical mycobacteria, <i>Salmonella</i> , and <i>Pseudomonas</i> infections
Phagocyte	CGD	Recurrent abscesses (<i>Staphylococcus aureus</i> , <i>Burkholderia cepacia</i> , <i>Aspergillus</i> spp.)
Complement	C5-C9	Recurrent <i>Neisseria meningitidis</i> infections

CGD, chronic granulomatous disease; CVID, common variable immunodeficiency; IFN, interferon; IL, interleukin; SCID, severe combined immunodeficiency; XLA, X-linked agammaglobulinemia.

Table 92-3 Screening Tests for Immune Function

Immune Function	Quantitative Assays	Functional Assays
Cellular immunity	<u>CBC with differential*</u> Flow cytometry CD3 ⁺ CD4 ⁺ CD3 ⁺ CD8 ⁺ CD16 ⁺ CD56 ⁺ FISH for 22q11 and 10p11 deletion	Cutaneous delayed hypersensitivity Enzyme assays (ADA, PNP) NK cell cytotoxicity assay
B cells	Flow cytometry CD19 ⁺ or CD20 ⁺	<u>IgG, IgA, IgM levels</u> Specific antibody response to immunization
PMN	<u>CBC with differential</u> Flow cytometry LFA-1 (CD18/CD11a) CD15	Oxidase function (NBT, DHR, chemiluminescence) Enzyme assays (MPO, G6PD) Phagocyte function Chemotaxis
Complement	C3, C4 Specific complement components Complement split products	<u>AH₅₀</u> (alternative pathway) <u>CH₅₀</u> (classical pathway)

*Preferred initial screening tests are underlined.

ADA, adenosine deaminase; CBC, complete blood count; DHR, dihydrorhodamine; FISH, fluorescence in situ hybridization; G6PD, glucose 6-phosphate dehydrogenase; Ig, immunoglobulin; LFA-1, lymphocyte function-associated antigen 1; MPO, myeloperoxidase; NBT, nitroblue tetrazolium; NK, natural killer; PMN, polymorphonuclear leukocytes; PNP, purine nucleoside phosphorylase, a key T-cell enzyme.

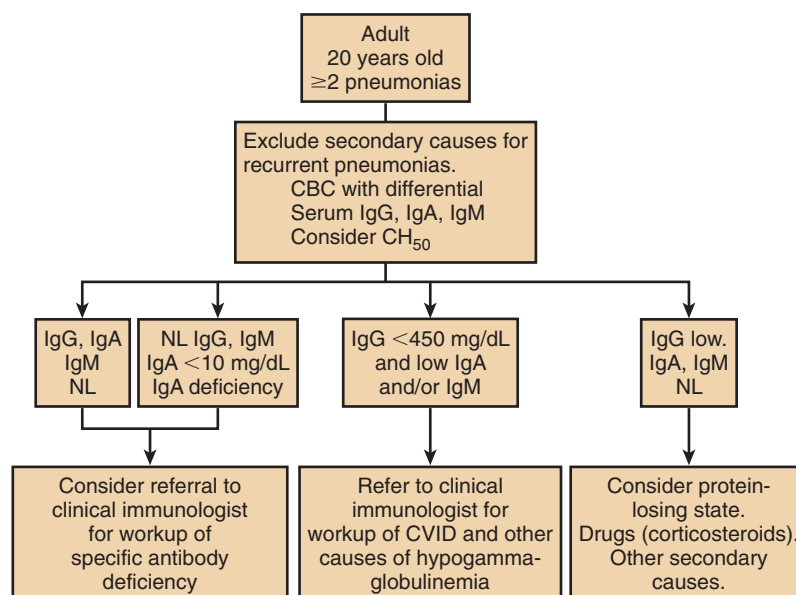

Figure 92-1 A diagnostic algorithm for an adult with possible primary immunodeficiency. In an adult, with CVID as the most common diagnosis, a screening approach is shown. It would be unusual for an adult to present with a phagocytic defect or combined immunodeficiency; thus, antibody levels, complete blood count, and complement are appropriate for initial screening. If CH_{50} is ordered, an absent CH_{50} is consistent with complement deficiency and should result in referral to the clinical immunologist, whereas a low CH_{50} is consistent with complement consumption. CVID, common variable immunodeficiency; NL, normal; R/O, rule out.

ANTIBODY DEFICIENCIES

The quantitative measurement of *immunoglobulin G* (IgG), *immunoglobulin A* (IgA), and *immunoglobulin M* (IgM) is the single best test to screen for primary antibody deficiencies.⁸ An abnormality in the level of one or more of these classes of immunoglobulins is present in the majority of patients with primary antibody deficiencies. The pattern of the levels of IgG, IgA, and IgM gives important insight into the likely etiology of the antibody deficiency. For example, clinical immunologists are frequently consulted about whether a patient on corticosteroids has a primary antibody deficiency. In steroid-induced hypogammaglobulinemia, IgG levels are usually only moderately depressed (usually > 400 mg/dL) and the magnitude of reduction reflects the dosage and duration of corticosteroid usage.⁹ IgA and IgM levels tend to be preserved. In CVID, IgG levels are usually more profoundly depressed (<400 mg/dL), IgA levels are reduced (<10 mg/dL) in 70% of patients, and IgM levels are reduced (<25 mg/dL) in more than 80% of patients.⁸ Finally, in comparison with patients with steroid-induced hypogammaglobulinemia, patients with CVID have a more profound defect in their ability to make antigen-specific antibodies following immunization.¹⁰

The enumeration of B cells, typically measured by flow cytometry using monoclonal antibodies directed against the CD19 or CD20 surface antigens, may also provide clues to the type of B-cell immunodeficiency present. In XLA and *autosomal recessive* (AR) forms of agammaglobulinemia, the numbers of B cells are usually severely reduced. In contrast, the number of B cells in CVID is frequently, but not always, normal. It is important to obtain a careful medication history because novel agents such as rituximab, a chimeric monoclonal antibody directed against CD20, can lead to profound decreases in B-cell numbers for months after treatment.

In assessing response to immunization, it is important to immunize with both a protein and *polysaccharide* (PS) antigen and to assess the response 4 to 6 weeks post immunization. The immunologic requirements to make antibodies (e.g., T-cell help, cytokine requirements) in response to immunization with a protein or PS antigen differ. Some patients with normal quantitative immunoglobulins or selective IgA deficiency exhibit a selective inability to make antibody to PS, but not to protein antigens. This immunologic defect (specific antibody deficiency) results in recurrent sinopulmonary infections and, in selected instances, may require replacement immunoglobulin therapy.

Protein antigens commonly used to assess specific antibody responses include tetanus and diphtheria toxoids. The *Haemophilus influenzae type B* (Hib) vaccine in present use conjugates the capsular *polyribose phosphate* to a protein carrier. Therefore, quantitation of antibodies to *H. influenzae* following immunization with the Hib vaccine measures competence of the immune system to make specific antibodies to a protein, not to PS antigens. Many adults have not been immunized to Hib, making the Hib vaccine particularly useful in the evaluation of this group of patients.

PS antigens used to test antibody responses are available in two unconjugated vaccines: the pneumococcal PS and *Neisseria meningitidis* vaccines. (Some pneumococcal vaccines are conjugated to a protein carrier and do not measure a response to the PS antigen [e.g., Prevnar]). When using the pneumococcal vaccine, the measurement of antibody responses to several (12 or more) capsular antigens is indicated. There is considerable controversy about what constitutes a normal response to the pneumococcal vaccine, and a clinical immunologist should make the interpretation of specific antibody responses.^{11,12} Finally, children younger than 2 years of age frequently do not make antibody responses to PS antigens. Thus, the use of PS vaccines to

diagnose antibody-deficient states in this age group is not indicated.

CELLULAR IMMUNODEFICIENCY

Many patients with impaired cellular immunity will have either reduced T-cell numbers, abnormal T-cell function, or both (see Table 92-3). T-cell numbers are easily screened by flow cytometry. The CD3 antigen measures the total number of T cells, whereas CD4 and CD8 antigens are present on the T-helper and T-cytotoxic subsets, respectively. T-cell function is easily assessed by testing cutaneous *delayed-type hypersensitivity* (DTH). In the DTH test, a small amount of an antigen is injected into the dermis and a positive reaction is indicated by induration (>2 mm) 48 to 72 hours later at the site of the injection. Antigens such as tetanus toxoid, *Candida*, and *Trichophyton* are frequently used because most individuals will have had a prior immune response to these antigens. However, DTH responses are frequently absent in normal infants, and in vitro assays of T-cell function are indicated in this group of patients.¹³ The measurement of *natural killer* (NK) cell numbers (CD16⁺/CD56⁺) and function is indicated in the evaluation of infants for possible SCID or of patients with recurrent, severe herpesvirus infection. The pattern of abnormalities in the numbers of specific lymphocyte subpopulations (T cells, NK cells, B cells) is helpful in identifying the molecular abnormality in infants with SCID (Table 92-4).

COMPLEMENT DEFICIENCIES

The screening tests for complement deficiency states associated with increased infections are the CH₅₀ and AH₅₀, which measure the integrity of the classical and alternative pathways of complement activation, respectively¹⁴ (see Table 92-3). The CH₅₀ measures the volume (or dilution) of serum required to lyse 50% of the sample erythrocytes; AH₅₀ is a similar measure testing the alternative pathway. Abnormalities in CH₅₀ or AH₅₀ could be due to inappropriate activation and consumption of complement or to deficiencies in individual components of complement. Many times these possibilities can be distinguished by the measurement of two or more individual components of the classical or alternative complement pathway and the measurement of complement split products. Complement *consumption* is indicated by low levels of more than one component of complement,

which may vary over time, and by the elevation of complement split products. In contrast, complement *deficiency* states show fixed, depressed levels of individual members of the complement pathway with normal levels of complement split products.

PHAGOCYTE DEFICIENCIES

The initial screening test for phagocytic defects includes a complete blood count, with quantitation of leukocyte number and morphology (see Table 92-3). The *dihydrorhodamine* (DHR) test has replaced the *nitroblue tetrazolium* (NBT) test in most centers to diagnose defects in the generation of superoxide, such as is seen in *chronic granulomatous disease* (CGD).¹⁵ Advantages to the DHR test include its ease, rapidity, and reproducibility, along with the capacity to detect CGD carrier states. Both the NBT and DHR tests measure the ability of phagocytes to generate superoxide free radicals. In the DHR test, phagocytes are loaded with a fluorescent dye (DHR) and activated with phorbol myristate acetate. Activated phagocytes then produce superoxide free radicals that reduce DHR, leading to a change in fluorescence that is quantitated by flow cytometry. Other functional assays for phagocytes include enzyme assays for myeloperoxidase and glucose 6-phosphate dehydrogenase, chemotaxis assays, phagocytic tests, and bactericidal assays. Abnormalities in the adhesion molecules CD18 and CD15 that result in leukocyte adhesion deficiency 1 and leukocyte adhesion deficiency 2, respectively, are detected by flow cytometry.

DEFICIENCY IN BOTH CELLULAR IMMUNITY AND ANTIBODY PRODUCTION

SEVERE COMBINED IMMUNODEFICIENCY

SCID is a syndrome that encompasses a variety of molecular defects that result in absent or severely impaired T-cell and B-cell number and function.^{16,17} One commonly used method to classify SCID is based on whether the molecular defects decrease the numbers of T, B, and/or NK cells (see Table 92-4).

The molecular defects that lead to SCID include mutations that lead to abnormalities in cytokine signaling (e.g., the common γ chain [γ c] of the *interleukin* [IL]-2 receptor; *Janus activating kinase 3* [JAK3], or IL-7 receptor) and T-cell receptor signaling (e.g., CD45, ZAP-70, CD3y, CD3e, CD3C); defective T-cell and B-cell receptor gene recombination (e.g., *RAG1*, *RAG2*); defective nucleotide salvage pathway (*adenosine deaminase* [ADA] deficiency); and defects in the expression of major histocompatibility complex class I or class II molecules. X-linked SCID caused by the mutation in the common γ c of the IL-2 receptor is the most common form of SCID, accounting for approximately 50% of all cases. The γ c of the IL-2 receptor is utilized by several other cytokine receptors, including the receptors for IL-4, IL-7, IL-11, IL-15, and IL-21. Consequently, the immunodeficiency due to mutation of the γ c is due to the combined effects of loss of function in all of these cytokine receptors.

Table 92-4 Common Etiologies of Severe Combined Immunodeficiencies

Form of SCID	Prevalence	Absent Cell Type	Inheritance
Common γ chain IL-2 receptor deficiency	45%–50%	T/NK	X-linked
IL-7 receptor	10%	T	AR
ADA deficiency	15%	T/B/NK	AR
RAG1/RAG2	5%–8%*	T/B	AR
JAK3	5%–10%	T/NK	AR

*Total prevalence of patients with mutations in either *RAG1* or *RAG2* gene. ADA, adenosine deaminase; AR, autosomal recessive; JAK, Janus activating kinase; SCID, severe combined immunodeficiencies.

Atypical forms of SCID may also result from mutations of genes associated with classical SCID that are *hypomorphic*, meaning that the mutation leads to a protein with reduced function. One such example is the Omenn syndrome, whose clinical manifestations include severe skin disease (erythroderma, granuloma, and desquamation), hepatosplenomegaly, lymphadenopathy, and high IgE levels. Additionally, there are other single gene defects that can lead to combined immunodeficiencies such as Wiskott-Aldrich syndrome, DiGeorge syndrome, Ataxia-telangiectasia, X-linked lymphoproliferative disorder, and some forms of hyper-IgM syndrome. For purposes of this chapter, these latter diseases are discussed separately from SCID.

The clinical presentation of SCID is characterized by severe infections, most commonly of the respiratory and gastrointestinal tract in early infancy. Infections are caused by common and opportunistic pathogens, and disseminated infections are frequent. Other common manifestations of the syndrome include oral thrush, persistent diarrhea, interstitial pneumonitis, impaired growth, and the absence of lymph nodes. Engraftment of maternal T cells in an infant with SCID can lead to graft-versus-host disease. The prompt treatment of infection, administration of IVIG, and prophylaxis against *Pneumocystis jirovecii* are indicated until HSCT can take place. In the event blood transfusions are necessary, only irradiated, *cytomegalovirus* (CMV)-negative blood should be used. No live virus vaccinations should be given to infants with known or suspected SCID.

Early diagnosis and treatment by HSCT (<3.5 months of age) of SCID leads to a markedly improved prognosis.² Therefore, it is incumbent on the physician to make a prompt diagnosis of SCID. Several U.S. states, starting with Wisconsin in 2008, now screen all newborns for SCID.^{17a,17b} The disease has been added to the Uniform Panel of newborn screening tests recommended by the U.S. government.^{18,19} In the absence of newborn screening, the lack of a thymic shadow on chest radiograph and severe lymphopenia (<2500/ μ m) in an infant with recurrent infections should prompt further studies to exclude the diagnosis of SCID. The diagnosis of SCID is confirmed by enumerating lymphocytes and subsets of naïve T cells, B cells, and NK cells by flow cytometry and detecting a deficiency in the capacity of T cells to proliferate to mitogens.

HSCT is the preferred treatment for SCID, except for SCID due to ADA deficiency.^{19a} For SCID due to ADA deficiency, the administration of polyethylene glycol-ADA is an alternative treatment. In addition, for X-linked SCID and SCID due to ADA deficiency, gene therapy has been successfully used.^{20,21} However, the retroviral vectors used in these earlier studies led to insertional mutagenesis with activation of the proto-oncogene LMO-2 leading to $\gamma\delta$ T-cell leukemia in some patients.^{22,23} Trials of gene therapy for SCID using lentiviral vectors, which are safer in preclinical studies, are ongoing.^{24,25,25a}

ANTIBODY DEFICIENCIES

IMMUNOGLOBULIN A DEFICIENCY

The prevalence of IgA deficiency varies among different ethnic groups, but the overall prevalence is approximately

1 in 400 live births.^{26,27} The etiology of IgA deficiency remains obscure. Rarely, IgA deficiency may evolve into CVID, and families may develop both IgA deficiency and CVID, suggesting a common genetic basis.²⁸ Medications, in particular anticonvulsants, infrequently cause IgA deficiency or panhypogammaglobulinemia, and immunoglobulins may normalize with discontinuation of the drug.

There is considerable controversy as to whether IgA deficiency alone predisposes people to infection.^{26,29} Most patients with IgA deficiency do not have increased frequency of infections and are often discovered during an evaluation for problems unrelated to infection. However, some patients with IgA deficiency have recurrent infections, predominantly respiratory tract infections.³⁰ Whether IgG subclass deficiency and/or deficiencies in mannose-binding lectin identify a subgroup of patients with IgA deficiency who are more prone to infection is not clear.³¹ Unlike patients with more severe forms of antibody deficiency such as CVID or X-linked agammaglobulinemia, replacement therapy with IVIG is not warranted with isolated IgA deficiency. In patients with IgA deficiency and concomitant IgG subclass deficiency who have recurrent and persistent respiratory tract infections, determination of the antibody response following vaccination should be used to ascertain if IVIG therapy is warranted.³²

Clinical manifestations of IgA deficiency are highly variable. Infectious complications of IgA deficiency include recurrent upper (otitis media, sinusitis) and lower respiratory tract infections.³⁰ Gastrointestinal tract infections, in particular recurrent giardiasis, may be present. The prevalence of atopic diseases (asthma, allergic rhinitis, eczema) and autoimmune diseases (systemic lupus erythematosus, celiac disease, rheumatoid arthritis) is increased in patients with IgA deficiency.

Serologic studies in IgA deficiency may be subject to false-positive and false-negative results due to the presence of heterophile antibodies.³³ Heterophile antibodies react to the immunoglobulins of other species and may be increased in IgA-deficient patients due to increased exposure of antigens at the gut mucosa to the systemic circulation. The diagnosis of celiac disease in patients with IgA deficiency is problematic because the most specific serologic assay for celiac disease, IgA anti-tissue transglutaminase, is absent in IgA-deficient patients. Therefore, other assays should be performed in the laboratory assessment of celiac disease in IgA-deficient patients.

X-LINKED AGAMMAGLOBULINEMIA

XLA (Bruton agammaglobulinemia) is a primary antibody deficiency with an estimated prevalence of 1 in 190,000 male live births.³⁴ Mutations in the gene for *Bruton tyrosine kinase* (Btk) are responsible for this immunodeficiency.³⁵ Btk is required for B-cell receptor signaling, playing a key role in the phosphorylation of phospholipase $C\gamma 2$. Btk function is essential for the survival and differentiation of immature B cells. Consequently, nearly all patients with XLA have a marked deficiency in B cells (<2% of lymphocytes) and profound panhypogammaglobulinemia. XLA accounts for approximately 85% of inherited forms of agammaglobulinemia due to defects in early B-cell development, with AR forms of antibody deficiency accounting for the

remainder.³⁵ The clinical manifestations of the AR forms of agammaglobulinemia are similar to XLA.

In addition to B cells, Btk is expressed on myeloid cells and platelets but not on NK cells or T cells. Consequently, T-cell function is normal in XLA, which contrasts with some other antibody deficiency disorders such as CVID or some forms of the hyper-IgM syndrome in which abnormalities in cellular immunity are frequently present. Up to 25% of patients with XLA present with neutropenia, which may contribute to the severity of infection.³⁶

Small or absent tonsils and lymph nodes are the only characteristic physical findings in XLA. The vast majority of patients with XLA have recurrent upper (otitis media; sinusitis) and lower respiratory tract infections, with more than 50% of patients having recurrent infections by 1 year of age and nearly all patients symptomatic by age 5. The most common pathogens causing pneumonia are encapsulated bacteria (*S. pneumoniae* and *H. influenzae*).³⁴ Respiratory tract infections due to atypical bacteria such as *Mycoplasma pneumoniae* or *Ureaplasma urealyticum* are also frequently encountered. Gastrointestinal tract infections develop in nearly one quarter of patients and are most commonly due to *Giardia lamblia*, although bacteria (*Salmonella* spp., *Shigella* spp., *Campylobacter fetus*, *Helicobacter pylori*) and viruses (*Rotavirus*, enteroviruses) are also frequently isolated. Disseminated infections that include encephalitis due to infection with enteroviruses, in particular echovirus, were a major cause of mortality in patients with XLA. However, these infections appear to be declining with use of high-dose immunoglobulin replacement therapy.³⁴

The pulmonary complications of XLA continue to be a major cause of morbidity and mortality and include bronchiectasis and cor pulmonale.³⁴ Complete pulmonary function tests (if possible) and a *high-resolution computed tomography* (HRCT) scan of the chest are indicated in the initial evaluation of these patients. High-dose IVIG has been shown to decrease pulmonary infections in these patients but may not prevent the progression of bronchiectasis. Bronchiectasis, if detected, should be treated with daily pulmonary hygiene (e.g., inhaled β -agonists, hypertonic saline, chest physiotherapy) and aggressive antimicrobial therapy for intercurrent pulmonary infections. The efficacy of rotating antibiotics or chronic antimicrobial therapy in patients with bronchiectasis and immunodeficiency is unknown.

IVIG and *subcutaneous infusion of gamma globulin* (SCIG) are the most commonly used forms of antibody replacement for the treatment of profound antibody deficiencies such as XLA and CVID. Compared with IVIG, SCIG has far fewer infusion-related adverse reactions.³⁷ High doses of gammaglobulin (400 to 600 mg/kg/month) are superior in preventing infections compared with “conventional” doses of IVIG (100 to 150 mg/kg), and the optimal dose should be based on prevention of infection rather than level of IgG.^{38,39} Intercurrent sinopulmonary infections should be aggressively treated with appropriate antimicrobial therapy to include coverage of common encapsulated bacteria, as well as coverage of atypical bacterial pathogens (*Mycoplasma* spp., *Ureaplasma*).⁴⁰

A common mistake in managing patients with profound antibody deficiencies (e.g., XLA, CVID) is the inappropriate use of serologic assays in the diagnosis of infectious disorders.

With the exception of IgA and IgG subclass deficiency, patients with antibody deficiency do not make specific antibodies in response to exogenous antigens. Therefore, the use of diagnostic studies to detect specific antibodies against pathogens is unreliable and, if positive, usually reflects antibodies present in the IVIG used to treat such patients. Diagnostic studies that detect microbial antigens or nucleic acids (polymerase chain reaction assays) from the pathogen must be used in place of serologic assays.

COMMON VARIABLE IMMUNODEFICIENCY

CVID, also known as acquired hypogammaglobulinemia, is a primary immunodeficiency affecting approximately 1:20,000 to 1:50,000 live births.⁴¹ CVID is a clinical syndrome representing a family of disorders that exhibit a common phenotype. Although highly variable, the mean onset of symptoms in patients with CVID is in the third decade of life. There remains a considerable delay, up to 10 years, between the onset of symptoms and the diagnosis of CVID.^{8,42,43} Unlike in XLA, T-cell abnormalities are common in patients with CVID and contribute to the more protean clinical manifestations of this disease.⁸ The diagnosis of CVID should be considered in any person older than age 4 with recurrent respiratory tract infections (i.e., two or more confirmed pneumonias).

The etiology in the vast majority of cases of CVID is unknown. Heterozygous mutations in the gene encoding TACI (a *tumor necrosis factor* [TNF] receptor family member involved in isotype switching in B cells) are found in approximately 5% to 10% of patients and markedly increase the risk of developing CVID while biallelic mutations always lead to the development of CVID.⁴⁴⁻⁴⁷ Mutations in *inducible T-cell co-stimulator* (ICOS), *CD19*, *CD20*, *CD21*, *CD81*, and *BAFFR* are other monogenic causes of CVID in a small percentage of patients.⁴⁸⁻⁵² Collectively, mutations or polymorphisms of these genes account for less than 10% to 15% of all cases of CVID.

The laboratory evaluation of patients with CVID demonstrates the complex nature of the disease.⁸ The definitive diagnosis of CVID requires the demonstration of a low serum level of IgG (usually < 450 mg/dL), low serum level of IgA and/or IgM, impaired capacity to make specific antibodies in response to immunization or infection, and the exclusion of other primary or secondary antibody deficiencies. B-cell numbers are variable in CVID and, if reduced, may indicate a poor prognosis.⁸ B-cell subset analysis by flow cytometry is valuable in predicting risk to develop certain complications of CVID. Low numbers of switched memory B cells (CD27⁺, IgM⁻, IgD⁻) in the peripheral blood are frequently found in patients with splenomegaly and systemic granulomatous disease involving the lungs.⁵³⁻⁵⁶ T-cell abnormalities are found in approximately 40% of patients and include anergy, T-cell lymphopenia, and poor in vitro proliferative responses to mitogens and antigens.

Nearly all patients present with recurrent upper or lower respiratory tract infections, including bronchitis, sinusitis, otitis media, and pneumonia. Common pathogens include encapsulated (*H. influenzae*, *S. pneumoniae*) or atypical (*Mycoplasma* spp.) bacteria.^{8,40,57} Pulmonary infections can also be caused by gram-negative rods, in particular in patients with long-standing CVID or impaired cellular

immunity. Opportunistic infections develop in less than 10% of patients.³⁹ Because patients with CVID appear to be particularly susceptible to infections with atypical bacteria such as *Mycoplasma* spp. and *Ureaplasma* spp., antimicrobial therapy of respiratory tract infections that is effective against these organisms should be used.⁴⁰ Apart from respiratory tract infections, joint and bone infections due to these organisms have also been reported. Gastrointestinal tract infections with pathogens similar to those found in XLA (*Campylobacter jejuni*, *Salmonella* spp., *G. lamblia*) are also common.⁸ The prevalence of hepatitis is increased in CVID (in $\approx 12\%$ of patients). The prognosis from hepatitis C is poor and may be rapidly progressive in patients with CVID.

The mortality of CVID due to common infectious pathogens has declined with the increased use of high-dose immunoglobulin replacement.⁵ Complications such as chronic lung disease, malignancy, liver, and gastrointestinal tract disease are now the most common risk factors for early mortality.⁵⁶ Although patients with CVID are unable to make antibodies to foreign antigens, they exhibit an increased propensity to make autoantibodies. Consequently, the prevalence of autoimmune disorders, in particular *idiopathic thrombocytopenic purpura* (ITP) and *autoimmune hemolytic anemia* (AHA) is increased.^{8,58} Oral corticosteroids, the use of immunomodulatory dosages of IVIG (2 g/kg per month), and rituximab have been used to treat ITP and AHA in patients with CVID.⁵⁹

Patients with CVID are at high risk for developing malignancy. In particular, the prevalence of non-Hodgkin lymphomas and gastric carcinoma are increased in CVID and are a major cause of morbidity and mortality in this disorder.⁶⁰ Careful periodic examination of the lymph nodes and spleen is important because patients with CVID also frequently have adenopathy and splenomegaly that are nonmalignant in nature. The use of periodic abdominal *computed tomography* (CT) scans to assess spleen size and/or the presence of intra-abdominal and retroperitoneal adenopathy, along with upper and lower endoscopic evaluation for gastrointestinal symptoms, may also be useful.

The pulmonary disorders associated with CVID are complex and a major cause of mortality.⁶¹⁻⁶⁵ Bronchiectasis is the most common pulmonary disorder, seen in more than 20% of patients. It is not clear whether high-dose gamma globulin replacement therapy can prevent the development of bronchiectasis in patients with CVID.⁴³ On the basis of studies of patients with bronchiectasis without immunodeficiency, bronchiectasis in patients with CVID is managed with standard approaches including mobilization of pulmonary secretions through the use of medications such as hypertonic saline or β_2 -agonists combined with chest physiotherapy and the chronic administration of macrolides.⁶⁶⁻⁶⁸ Bronchiolitis obliterans organizing pneumonia (now termed *cryptogenic organizing pneumonia*) has also been described and appears to respond to corticosteroid therapy.^{69,70}

Diffuse interstitial lung disease, including granulomatous lung disease, *lymphocytic interstitial pneumonia* (LIP), follicular bronchiolitis, and cryptogenic organizing pneumonia (bronchiolitis obliterans with organizing pneumonia), develops in approximately 10% to 25% of patients with CVID; these diffuse interstitial lung diseases are refractory to IVIG therapy.^{61,62-65,71} The presence of granuloma-

tous lung disease led some to believe that this represents a form of sarcoidosis.⁷² Common features shared with sarcoidosis include the systemic nature of the disease, frequent presence of mediastinal and hilar adenopathy, and noncaseating granulomas in the lungs and other organs. However, it now appears likely that this lung disorder represents a distinct disease entity.^{61,65} Unlike in sarcoidosis, both granulomatous and lymphoproliferative histopathologic patterns (LIP, follicular bronchiolitis, and lymphoid hyperplasia) often appear together. Thus, the term *granulomatous-lymphocytic interstitial lung disease* (GLILD) has now been used to characterize the pulmonary disorder in CVID.⁵¹ In comparison with sarcoidosis, GLILD exhibits a lack of spontaneous remission of lung disease; a poor response to corticosteroid therapy; panhypogammaglobulinemia with low numbers of switched memory B cells; a high prevalence of autoimmune disease, in particular ITP; a history of recurrent infections; and large areas of organizing pneumonia on biopsy.^{72a} Patients with GLILD and CVID more frequently have hepatosplenomegaly, typically have diffuse adenopathy, and are at increased risk for developing non-Hodgkin lymphoma.^{61,65} HRCT of the chest is indicated in the evaluation of patients with GLILD and demonstrates numerous abnormalities, including mediastinal adenopathy; diffuse ground-glass, nodular opacities; and areas of consolidation. The parenchymal abnormalities in GLILD are typically in the lower lung zones, which also contrasts with sarcoidosis.⁷³

The etiology of GLILD is unknown. The overproduction of TNF- α may contribute to the granulomatous disease in these patients.⁷⁴ Case reports have demonstrated that the use of TNF- α antagonists may lead to regression of granulomatous disease in patients with CVID, lending further support to this hypothesis.⁷⁵ Limited anecdotal experience suggests that the GLILD may also respond to low-dose cyclosporine therapy.⁷⁶ In a retrospective study of seven patients, the use of rituximab and azathioprine improved the radiographic abnormalities and pulmonary function of patients with CVID and GLILD without an increased incidence of infection.⁷⁷ This approach, although promising, needs to be validated in a properly controlled prospective study.

The combination of CVID in conjunction with a thymoma is known as Good syndrome.^{78,79} Whether this disorder is distinct from CVID or represents another manifestation of the disease is unclear. The thymoma is often not apparent on routine chest radiograph. Immune evaluation frequently demonstrates low numbers of CD4 T cells and B cells. Autoimmune disorders and opportunistic infections appear to be more common in this group of patients, and diffuse pan-bronchiolitis has also been described.⁸⁰ Resection of the thymoma is recommended, although this will not resolve the immunodeficiency or autoimmunity.⁷⁸

Due to the complexity of the pulmonary disease, patients with CVID should undergo periodic chest radiographs, full pulmonary function tests, and HRCT scans of the chest. In the diagnostic evaluation of patients with GLILD or other forms of interstitial lung disease, it is essential to obtain sufficient tissue to exclude the diagnosis of lymphoma or cryptogenic organizing pneumonia. Therefore, we perform video-assisted thoracoscopic lung biopsies in the evaluation of patients with diffuse interstitial lung disease and CVID.⁷⁷

SPECIFIC ANTIBODY DEFICIENCY

Specific antibody deficiency (SAD) is a primary antibody deficiency disorder that is characterized by normal levels of IgG, IgA, and IgM but an inability to make specific antibodies, most commonly in response to PS antigens such as Pneumovax.^{81,82} Patients with specific antibody deficiency present with recurrent sinopulmonary infections, similar to other forms of hypogammaglobulinemia. The diagnosis of SAD is made by measuring an absence of specific antibody responses following immunization with PS vaccines, most commonly the unconjugated pneumococcal vaccine. Cellular immunity is normal in this disorder. The initial treatment of SAD is similar to IgA deficiency; however, IVIG may be indicated in patients with SAD who have recalcitrant sinopulmonary infections and fail more conservative treatment.

IMMUNOGLOBULIN G SUBCLASS DEFICIENCY

IgG subclass deficiency is defined by normal total serum IgG levels with a low level of one or more IgG subclasses. There are four isotypes of IgG in humans: IgG1, IgG2, IgG3, and IgG4. The predominant subclass is IgG1, accounting for more than 60% of the total IgG. In some patients evaluated for recurrent sinopulmonary infections, low levels of one of the IgG subclasses are found. However, the significance of IgG subclass abnormality is unclear.^{83,84} Some believe that isolated IgG subclass deficiencies predispose patients to recurrent sinopulmonary infections. In contrast, IgG subclass deficiencies, including genetic deletions of IgG subclass loci, are well documented in healthy individuals.⁸⁵ Because the clinical significance of isolated IgG subclass deficiencies is unclear, the measurement of IgG subclasses is not warranted in the initial evaluation of patients with recurrent sinopulmonary infections. In patients with an isolated IgG subclass deficiency and recurrent infections, the decision to use IVIG should be based on antibody responses following vaccination.

X-LINKED LYMPHOPROLIFERATIVE SYNDROME

X-linked lymphoproliferative syndrome (XLP), or Duncan disease, is a rare primary immunodeficiency characterized by an extreme sensitivity to infection with *Epstein-Barr virus* (EBV). Approximately 80% of XLP (XLP-1) is caused by mutations in the adaptor protein gene *SH2D1A* (also known as *SAP*; the gene for *slam-associated protein*).^{86,87} The *SH2D1A* adaptor protein affects multiple intracellular signaling pathways in several different lymphocyte subpopulations, including T cells, B cells, and NK cells, a property that leads to the complex immunologic abnormalities seen in these patients. Mutations in the *X-linked inhibitor of apoptosis* gene (*XIAP*) account for the remainder of patients with XLP (XLP-2), which results in premature apoptosis of lymphocytes in response to a variety of stimuli.⁸⁷ Patients with XLP have a unique predisposition to infection with EBV, an infection that triggers the immunodeficiency in the vast majority of cases. Approximately 60% of patients with XLP present with overwhelming EBV infection leading to hemophagocytic lymphohistiocytosis. Therefore, the diagnosis of XLP should be considered in males with fulminant EBV

infections. The clinical phenotypes of XLP-1 and XLP-2 overlap with the exception that lymphoma is seen only in XLP-1 and splenomegaly is frequently the first clinical manifestation in XLP-2.^{88,89} Lymphomas or hypogammaglobulinemia develops following EBV infection in approximately 30% of patients with XLP-1. The only definitive therapy for XLP is HSCT,^{90,91} although IVIG is commonly used in an effort to prevent infections.

HYPER-IMMUNOGLOBULIN M SYNDROME

Hyper-IgM syndrome (HIGM) is a descriptive term that reflects a common laboratory abnormality (high serum IgM level with low serum IgA and IgG levels) found in several otherwise dissimilar types of immunodeficiencies (Table 92-5). Despite the name, high levels of IgM are inconsistently found in all forms of hyper-IgM syndrome.^{92,93} Furthermore, many believe that grouping these distinct immunodeficiencies together, some of which are intrinsic B-cell abnormalities, whereas others are complex combined cellular and humoral immunodeficiencies, leads to diagnostic confusion and is fundamentally flawed. Nevertheless, the classification remains widely used despite the obvious drawbacks. Although we group HIGM under “predominantly antibody deficiencies,” only mutations in *activation-induced cytidine deaminase* (*AICDA*)⁹⁴ or *uracil nucleotide glycosylase* (*UNG*)⁹⁵ result in primary immunodeficiencies that are largely due to antibody deficiency. The other forms of HIGM are complex cellular and humoral immunodeficiencies.

X-LINKED HYPER-IGM SYNDROME

The classic, *X-linked form of HIGM* (XHIGM), which accounts for approximately two thirds of cases, is due to a mutation in the *CD40 ligand* (*CD40LG*) gene.^{92,96} *CD40L* is inducibly expressed on activated CD4 T cells and interacts with *CD40*,

Table 92-5 Etiologies of Hyper-IgM Syndrome

Mutation	Inheritance	Clinical Phenotype
<i>CD40LG</i>	X-linked	Abnormal cellular immunity, neutropenia in 50%, early onset, recurrent sinopulmonary infections, <i>Pneumocystis jirovecii</i> pneumonia, chronic diarrhea due to <i>Cryptosporidium</i> infection, diarrhea, inflammatory bowel disease, autoimmunity
<i>CD40</i>	Autosomal recessive	Similar to <i>CD40LG</i> mutation
<i>NEMO</i> (<i>IKK-γ</i>)	X-linked	Impaired cellular immunity, variable serum levels of IgM or IgA, ectodermal dysplasia (most), recurrent pyogenic infections, viral infections, mycobacterial infections
<i>AICDA</i> or <i>UNG</i>	Autosomal recessive	Impaired humoral immunity, normal cellular immunity, later age of onset than other types of hyper-IgM syndrome, increased autoimmunity and lymphadenopathy
Unknown	Variable	Similar to <i>AICDA/UNG</i> mutations

AICDA, activation-induced cytidine deaminase; *AR*, autosomal recessive; *Ig*, immunoglobulin; *UNG*, uracil nucleotide glycosylase; see text for other abbreviations.

which is expressed on the surface of B cells. The interaction of CD40 on B cells with CD40L on activated T cells in conjunction with specific cytokines (IL-4) is required for immunoglobulin class switching. Consequently, mutations in *CD40LG* (or *CD40*) result in a failure to class switch, leading to defective production of the later immunoglobulin isotypes (IgG, IgA, immunoglobulin E [IgE]) and to persistence of IgM. CD40 is also expressed on monocytes and dendritic cells. The lack of CD40L T-cell interaction with CD40 on monocytes and dendritic cells also contributes to defective cellular immunity.⁹⁷ Mutations within the *CD40* gene are a rare cause of HIGM with a clinical phenotype similar to that of XHIGM. Serum levels of IgG are consistently low, and serum levels of IgA are reduced in the majority of patients. However, serum levels of IgM are inconsistently high in approximately 50% of patients.⁹² Antibody responses to immunization show a weak IgM response, without development of IgG- or IgA-specific responses and the absence of immunologic memory. The numbers of switched memory B cells (CD27⁺, IgD⁻, IgM⁻) are extremely low. Neutropenia is found in approximately 50% of patients and may respond to treatment with *granulocyte colony-stimulating factor* (G-CSF).

Patients with XHIGM have recurrent infections beginning early in life. More than half of patients with XHIGM are diagnosed by age 1 and nearly all by age 4. Pneumonia, frequently caused by infection with *P. jirovecii*, is common, seen in up to 80% of patients. Sinusitis, otitis media, and other respiratory tract infections are frequent. Intractable diarrhea, sometimes due to infection with *Cryptosporidium* or more frequently idiopathic, develops in nearly one third of patients. *Cryptosporidium* infection is also a major cause of sclerosing cholangitis in these patients. Infection of the central nervous system (encephalitis, meningitis), frequently due to infection with echovirus, is a major cause of morbidity and mortality. Treatment of XHIGM includes IVIG, prophylaxis against *P. jirovecii*, G-CSF for neutropenia, and consideration for HSCT.⁹⁸

Mutations of NF- κ B Essential Modifier

Hypomorphic mutations within the *NF- κ B essential modifier* (*NEMO*) gene, an X-linked gene, cause an immunodeficiency characterized by recurrent pyogenic infections, increased susceptibility to mycobacterial infections, and variable B-cell and T-cell abnormalities.^{99,100} *NEMO*, also known as IKK- γ , is part of the *I κ B kinase* (IKK) complex. IKK is responsible for phosphorylating the inhibitor of NF- κ B (I κ B), thereby releasing NF- κ B and allowing for its nuclear translocation. The protean immunologic and clinical manifestations due to mutations in *NEMO* reflect the importance of NF- κ B in multiple biologic processes. Approximately 80% of patients with mutations in *NEMO* have ectodermal dysplasia (abnormal teeth, decreased numbers of sweat glands, fine hair, frontal bossing). The ectodermal dysplasia in these patients is due to the inability of the ectodysplasin A receptor to induce the activation of NF- κ B. The susceptibility to mycobacterial infection is likely due to an inability of CD40 ligation to activate the NF- κ B pathway, leading to deficient IL-12 production by monocytes and dendritic cells and deficient *interferon* (IFN)- γ production by T cells and NK cells.¹⁰¹

Common immunologic screening tests of immune function may be normal in patients with *NEMO* deficiency. For

example, hypogammaglobulinemia or decreased specific responses to vaccination are found in approximately 60% of patients and high serum level of IgM in only 15% of patients. NK cell function has been reported to be abnormal in all patients with mutations in *NEMO* and may be a reasonable adjunctive screening test for this disorder.^{100,102}

Patients with *NEMO* mutations have severe infections usually beginning early in life. Common sites of infection include the lung, sinuses, middle ear, skin, and deep tissues (abscesses), blood (septicemia), gastrointestinal tract, and central nervous system. Pyogenic infections, frequently due to *Staphylococcus aureus*, *S. pneumoniae*, and *H. influenzae*, are seen in nearly 90% of patients. Mycobacterial infections (pneumonia, cellulitis, lymphadenitis, osteomyelitis) are seen in over 40% of patients and are usually caused by *Mycobacterium avium-intracellulare*. Severe viral infections (encephalitis, gastroenteritis, viremia) develop in approximately 20% of patients. Herpesviruses (herpes simplex virus, CMV) and adenoviruses are the most frequent viral pathogens. Opportunistic infections due to *P. jirovecii* or fungi develop in 10% of patients. Autoimmune disease—in particular, inflammatory colitis—afflicts approximately 20% of patients and can lead to intractable diarrhea. Treatment of patients with *NEMO* mutation frequently includes replacement gamma globulin and antimicrobial prophylaxis (*Pneumocystis*, mycobacteria). HSCT has had variable success in treating this disorder.¹⁰³

Mutations in *AICDA* or *UNG*

Mutations in *AICDA*⁹⁴ or *UNG*⁹⁵ are causes of AR forms of hyper-IgM. *AICDA* and *UNG* are essential for class switch recombination.¹⁰⁴ Hence, mutations in *AICDA* or *UNG* result in high serum levels of IgM, with low serum levels of IgG and IgA. Patients with mutations in either *AICDA* or *UNG* have a similar clinical phenotype with impaired humoral immunity and intact cellular immunity,¹⁰⁵ resulting in recurrent upper and lower respiratory tract infections and gastrointestinal tract infections. Lymphadenopathy is frequent, and autoimmunity (AHA and ITP) develops in approximately 20% of patients.

COMBINED IMMUNODEFICIENCIES OR SYNDROMIC IMMUNODEFICIENCIES

GATA-2 DEFICIENCY

An autosomal dominant inherited deficiency in *GATA2* underlies a unique combined immunodeficiency.^{106-112,112a} This rare disorder is also known as “dendritic cell, monocyte, B and NK cell deficiency,” familial myelodysplasia/leukemia with lymphedema, or MonoMac (monocytopenia with *M. avium* complex).

As the many names illustrate, the clinical manifestations, which usually present in adolescence or adulthood, are diverse. The immunologic features include a loss of dendritic cells, monocytes, NK cells, and B cells. Patients may develop pulmonary alveolar proteinosis not associated with anti-*granulocyte-macrophage* (GM)-CSF antibodies. Opportunistic

infections with *nontuberculous mycobacteria* (NTM), usually *M. avium* complex, are common. Infection with human papillomaviruses leads to warts and increased carcinomas in situ and cervical carcinoma. The bone marrow typically shows cytogenetic abnormalities, fibrosis, megakaryocyte dysplasia, and cytopenias; leukemia may develop. The monocytopenia may precede the clinical manifestations for years. HSCT is the only known cure for the disorder.¹¹³

DIGEORGE SYNDROME

DiGeorge syndrome (DGS), also known as 22q11.2 deletion syndrome or velocardiofacial syndrome, is one of the most common primary immunodeficiencies, found in approximately 1 in 3000 live births. The vast majority of patients with DGS have hemizygous deletion of varying degrees in chromosome 22q11.2, with rare cases due to deletion of 10p13. The molecular basis for many of the clinical manifestations of DGS appears to be deletions or mutations in *TBX1*, a T-box transcription factor important in embryonic development.¹¹⁴ Background genes are also thought to contribute to the phenotype in DGS because patients with identical deletions of 22q11.2 may have markedly different clinical phenotypes. Patients with DGS exhibit a characteristic facies that includes hypertelorism (wide spacing of the eyes), saddle nose, shortened philtrum, and low-set ears.¹¹⁵ Other common features of DGS include hypoplasia of the thymus and parathyroid glands, immunodeficiency, autoimmunity, cardiac abnormalities, velopharyngeal insufficiency, speech delay, developmental delay, and behavioral and psychiatric problems. Nearly 90% of infants diagnosed with DGS have cardiac abnormalities, and screening for DGS should be considered in an infant with any form of congenital heart disease, especially for those forms associated with DGS such as interrupted aortic arch, truncus arteriosus, tetralogy of Fallot, and anomalous aortic arch, with or without a ventral septal defect.^{41,115}

The immunodeficiency associated with DGS is highly variable and correlates with the degree of thymic hypoplasia.¹¹⁵⁻¹¹⁷ Patients with *complete* DGS, comprising less than 0.5% of the overall numbers of DGS patients, have a profound deficiency of T cells and T-cell function that requires thymic transplantation.¹¹⁸ In contrast, the majority of patients with DGS are referred to as *partial* DGS. Patients with partial DGS generally have a variable, usually non-life-threatening immunodeficiency. Patients with partial DGS may have moderately diminished numbers of T cells, and T-cell defects in these patients are usually mild with relatively normal in vitro and in vivo (i.e., delayed-type hypersensitivity skin tests) assessment of T-cell function. Intact thymic function is essential for deletion of autoreactive T cells. Consequently, patients with DGS have an increased prevalence of autoimmune disorders. Approximately 10% of patients with DGS have autoimmune disease. Juvenile arthritis, autoimmune hemolytic anemia, and immune thrombocytopenia are the most common autoimmune diseases in DGS. Studies of humoral function have yielded conflicting results. Abnormalities in humoral immunity requiring immunoglobulin replacement therapy are low in patients with DGS.¹¹⁹

Most patients with DGS tolerate live virus vaccines without complications, but an assessment of humoral and

cellular immune function should be performed before their administration. Infectious complications of partial DGS usually include recurrent sinopulmonary infections and otitis media. Structural abnormalities of the palate may contribute to recurrent sinus disease in these patients. Opportunistic infections are infrequent in partial DGS, although oral and esophageal thrush is seen. Patients with complete DGS are highly susceptible to infection with opportunistic pathogens, reflecting the much more severe cellular immunodeficiency. In these patients, attenuated live virus vaccines should be avoided and irradiated blood and blood products used to avoid graft-versus-host disease.

WISKOTT-ALDRICH SYNDROME

Wiskott-Aldrich syndrome (WAS) is an X-linked disorder characterized by recurrent infections, eczematous skin disease, and thrombocytopenia due to a mutation in the gene for *WAS protein* (WASp).¹²⁰ The function of WASp is complex but, through its interaction with a variety of adaptor molecules and kinases, WASp is involved in the integration of cytoplasmic signaling with the reorganization of the actin cytoskeleton. Consequently, WASp function is critical in the formation of the immunologic synapse (i.e., the molecular interface between lymphocytes and target cells or antigen-presenting cells), cellular motility, cellular trafficking, and protection against autoimmunity.¹²¹ Mutations in the gene for WASp cause four distinct diseases: (1) classic WAS; (2) X-linked thrombocytopenia; (3) intermittent thrombocytopenia; and (4) congenital X-linked neutropenia without other features of WAS.¹²² We limit this section to classic WAS.

The laboratory evaluation of patients with WAS usually demonstrates increased levels of serum IgE and IgA with a low level of IgM and normal level of IgG. Despite normal serum IgG levels, antibody responses following immunization to PS antigens are consistently impaired.¹²³ T-cell and NK-cell function is frequently abnormal, resulting in a partial combined immunodeficiency.¹²⁴ Decreased platelet counts, platelet function, and platelet size are hallmarks of the disorder and lead to the marked bleeding diathesis.

The clinical expression of WAS includes prolonged bleeding episodes beginning in infancy, recurrent pyogenic infections, autoimmunity, eczematous dermatitis, and an increased prevalence of EBV-related lymphomas. Upper and lower respiratory infections due to encapsulated organisms (*S. pneumoniae* and *H. influenzae*) are common and reflect the inability of patients with WAS to make specific antibody to PS antigens.¹²³ Pulmonary infections with opportunistic pathogens (*P. jirovecii*, herpesviruses) are also common. Infection and hemorrhage are common causes of death. The treatment of WAS includes aggressive treatment of intercurrent infections and administration of IVIG.¹²³ The thrombocytopenia usually responds to splenectomy. HSCT is the treatment of choice for WAS, with long-term survival rates over 70%.¹²¹ Recently, gene therapy using a lentiviral vector successfully treated three patients with WAS.²⁵

ATAXIA-TELANGIECTASIA

Ataxia-telangiectasia (AT) is an AR disorder due to a mutation in the *ATM* gene, which is involved in the repair of DNA

breaks.^{125,126} The clinical manifestations of AT include neurologic dysfunction (cerebellar ataxia, oculomotor apraxia, delayed motor development), telangiectasias, and immunodeficiency. Elevated levels of carcinoembryonic antigen and alpha-fetoprotein are present in nearly all patients with AT. The mutation in the *ATM* gene with an attendant increased radiosensitivity leads to the increased prevalence of malignancies such as lymphomas and epithelial tumors.^{125,126} Serum immunoglobulins are usually normal in AT, but selective IgA deficiency with impaired responses to polysaccharide antigens is common. Patients with AT develop recurrent sinopulmonary infections either due to the immunodeficiency or to a swallowing dysfunction, usually in infancy or early childhood. *Interstitial lung disease* (ILD) develops in approximately 20% of patients with AT. The optimal treatment of the ILD is not known, although corticosteroids have been used with some success.¹²⁷ There is no definitive treatment of AT. Antibody replacement has been used in patients to prevent the infectious complications of AT.

HYPER-IMMUNOGLOBULIN E SYNDROME

Hyper-IgE syndrome (HIES), also known as Job syndrome, is a syndrome characterized by recurrent skin and lung infections, severe eczema, and elevated levels of serum IgE. There are two forms of HIES. The more common *autosomal dominant* (AD) form of HIES (HIES type 1) is caused by mutations in the gene coding for the transcription factor *signal transducer and activator of transcription-3* (*STAT-3*) and has extra-immunologic features (connective tissue disorders, skeletal abnormalities) not present in the AR form (HIES type 2).¹²⁸ In addition, the AR form is complicated by a much higher incidence of cutaneous viral infections (HPV, *Molluscum contagiosum*) and neurologic complications and lacks the characteristic facies present in the AD form of HIES.^{128,129} Most of the AR forms of HIES have been found to be due to mutations and large deletions in the gene coding for the *dedicator of cytokinesis 8* (*DOCK8*), a protein involved in intracellular signaling.^{130,131} The remainder of this discussion focuses on the AD form of HIES.

The clinical features of HIES include the onset of moderate to severe eczema and eosinophilic pustular folliculitis in early infancy, skin infections (abscesses), mucocutaneous candidiasis, and recurrent pneumonias with pneumatoceles. Pneumatoceles are thought to develop as a consequence of disordered healing following primary infection of the lung. Common primary pathogens in HIES syndrome include *S. aureus*, *S. pneumoniae*, *H. influenzae*, and *Candida albicans*.

Secondary infection of the pneumatoceles with *Aspergillus* spp. or *Pseudomonas aeruginosa* often results in invasion of the pulmonary vasculature leading to pulmonary hemorrhage or central nervous system infection, which are major causes of death.¹³² The signs and symptoms of serious infection are frequently absent in patients with HIES. Abscesses may develop without signs of external inflammation (cold abscess) or pneumonia may be present with limited clinical symptoms. Bronchopulmonary fistulas leading to empyema frequently form following pulmonary surgery performed to manage the complications of HIES.¹³³

Several nonimmunologic features of HIES aid in the early diagnosis of this disease. Patients with HIES have a characteristic facies (coarse facial features with a protuberant mandible and forehead, hypertelorism, and a broad, fleshy nasal tip); retained primary teeth; severe osteopenia with fractures following minimal trauma; scoliosis; and hyperextensible joints.¹³⁴ More recently, it has been discovered that patients with HIES have the proclivity to develop aneurysms, in particular aneurysms of the coronary arteries.¹³⁵ The clinical significance of the aneurysms and proper management are unknown at this time.

The diagnosis of HIES cannot be made by routine assays of immunologic function. Typical abnormalities in the laboratory evaluation of patients with HIES include an elevated IgE (>2000 IU/mL) and eosinophilia. These laboratory abnormalities are not pathognomic of HIES and may be present in patients with severe atopic dermatitis. Elevated levels of serum IgE may wane with age, and a normal IgE level does not exclude the diagnosis of HIES.

An understanding of the molecular pathogenesis of HIES was significantly advanced with the discovery that mutations in the *STAT3* gene are the cause of this disorder. The *STAT3* gene codes for a transcription factor that is essential for the biologic activities of numerous cytokines, including IL-6 and IL-10.¹³⁶ The absence of the anti-inflammatory effects of IL-10 likely contributes to the dysregulated inflammatory response seen in HIES patients.¹³⁷ IL-6 is required for the genesis of CD4⁺ Th17 cells in humans and, therefore, there is a deficiency of Th17 cells in HIES.¹³⁸ Th17 cells are important in the defense against extracellular bacteria and fungi.¹³⁹

The treatment of HIES focuses on the prevention and prompt treatment of infection. Antimicrobial prophylaxis is often given to prevent infection with *S. aureus*. The role of antifungal prophylaxis is unknown. Optimal skin care, including the use of bleach baths, topical corticosteroids, and hydrating measures for eczema, is essential. IVIG or IFN- γ may benefit some patients.¹⁴⁰ In contrast to AD-HIES, HSCT has been used successfully to treat AR-HIES due to *DOCK8* deficiency.^{141,142}

PHAGOCYTIC CELL DISORDERS

Phagocytic defects can initially be categorized by whether the abnormalities are intrinsic or extrinsic to the phagocyte. *Intrinsic* phagocyte defects include defects in adhesion, chemotaxis, signaling, or killing. *Extrinsic* defects exist when phagocytic cell function is normal but auxiliary components necessary for optimal phagocytic function are absent such as immunoglobulins or complement.

There are several clinical indications for evaluation for phagocytic abnormalities, including neutropenia or the lack of neutrophilia with significant infection, infections with unusual or opportunistic pathogens (e.g., fungi such as *Aspergillus* or *Nocardia*; bacteria such as *Serratia marcescens* or *Burkholderia cepacia*); unusual sites of infection (e.g., recurrent osteomyelitis, abscesses in the brain, lung, or liver); systemic bacterial infections; recurrent skin or upper or lower respiratory tract infections; and cold abscesses. Apart from infection, patients with phagocytic defects may have ongoing chronic inflammatory responses

in the skin (e.g., eczematoid dermatitis) or mucous membranes (e.g., periodontitis, aphthous stomatitis) and disordered inflammatory responses leading to delayed or abnormal wound healing.

PHAGOCYTIC DEFECTS: INCREASED APOPTOSIS OF NEUTROPHILS

Cyclic Neutropenia and Congenital Agranulocytosis (Kostmann Syndrome)

Cyclic neutropenia is an autosomal dominant disorder due to a mutation in the gene for neutrophil *elastase-2* (ELA2). It is thought that mutations of *ELA2* induce premature apoptosis of neutrophil precursors by the induction of the unfolded protein response.¹⁴³ In cyclic neutropenia there is a regular, 21-day fluctuation of neutrophils and other blood components (platelets, monocytes, reticulocytes).^{143,144} During the periods of neutropenia, patients are predisposed to bacterial infection with pyogenic bacteria and opportunistic pathogens. The diagnosis of cyclic neutropenia should be suspected when a cyclic hematopoiesis and neutropenia coincides with recurrent infections. To document concurrent infection with neutropenia, serial complete blood counts (two to three times/week) for at least 6 weeks should be performed. Most cases of autosomal recessive congenital agranulocytosis (Kostmann syndrome) are due to mutations in the gene for HAX1, a mitochondrial protein thought to protect myeloid cells against apoptosis.¹⁴⁵ Other causes of congenital neutropenia include mutations in *WASP*, *GFI*, and *G6PC3*.¹⁴⁶

The clinical manifestations of congenital agranulocytosis typically begin in early infancy with life-threatening infections such as cellulitis, meningitis, perirectal abscesses, or sepsis.¹⁴⁷ Patients with congenital agranulocytosis have severe neutropenia with an absolute neutrophil count of fewer than 200 cells/mm³. The clinical manifestations of congenital agranulocytosis are more severe than those of cyclic neutropenia. The use of G-CSF is indicated in cyclic neutropenia and congenital agranulocytosis; it will increase neutrophil counts and reduce infection in the vast majority of patients with these disorders.¹⁴⁷ In patients with severe neutropenia unresponsive to G-CSF, HSCT should be performed.¹⁴⁸

DECREASED ADHERENCE/CHEMOTAXIS

Leukocyte Adhesion Deficiency Types I-III

The influx of leukocytes in general and neutrophils in particular to sites of infection is a complex process involving the production and release of neutrophils from the bone marrow, the activation of neutrophils by chemotactic factors with subsequent adhesion of neutrophils to the endothelium, and finally the transmigration of neutrophils through the endothelium of postcapillary venules. The first step in the egress of neutrophils from the circulation to sites of infection is mediated by the rolling (loose) adhesion of neutrophils to endothelium, mediated predominantly by CD15s (sialyl Lewis_x) on the neutrophil and its counterligands (E-selectin, P-selectin) on the endothelium. The following step in adhesion, which is of higher affinity, is

mediated predominantly by the interaction of the integrin *leukocyte function-associated antigen* (LEA-1; CD11a/CD18) on the leukocyte with its counter-ligand intracellular adhesion molecule-1 on the endothelium. Integrins are composed of two subunits (α , β), which are noncovalently associated. The common β chain of CD18 associates with CD11a (LEA-1), CD11b (Mac-1 or CR3), CD11c (gp150/95), and CD11d, which are expressed on a variety of leukocytes. Therefore, mutations in *CD18* reduce the expression of CD11a/CD18, CD11b/CD18, and CD11c/CD18, resulting in defects in the endothelial adhesion of all leukocytes. Defective expression of CD18 and CD15s lead to the primary immunodeficiencies *leukocyte adhesion deficiency type I* (LAD-I) and *LAD type II* (LAD-II), respectively.^{149,150} LAD type III, which is inherited in an autosomal recessive manner, is caused by a mutation in the gene encoding kindlin-3, a member of a protein family that may regulate integrin function.¹⁵¹⁻¹⁵³

LAD-I is divided into two broad categories on the basis of whether the deficiency of LEA-1 is severe (<0.5% of normal levels) or moderate (5% to 10% of normal levels).¹⁵⁴ Patients with a complete deficiency in LEA-1 expression often present in the neonatal period with delayed separation of the umbilical cord, infection of the umbilical cord (omphalitis), and severe infections of the skin, gingiva, and gastrointestinal and upper and lower respiratory tracts. Moderate deficiencies of LEA-1 result in a milder phenotype that may contribute to a delay in the diagnosis. Patients with LAD-I exhibit neutrophilia, even in the absence of systemic infection, due to the inability of leukocytes to adhere to the endothelium. The definitive diagnosis of LAD-I deficiency is made by the demonstration of extremely low levels of LEA-1 on neutrophils by flow cytometry. The treatment of LAD-I includes the aggressive use of antimicrobials in the treatment of infection. HSCT is the only definitive treatment for patients with severe deficiencies of LEA-1.^{149,155} Moderate deficiencies of LEA-1 may improve with recombinant IFN- γ therapy and chronic antimicrobial prophylaxis.

LAD-II is an extremely rare disorder characterized by developmental delay, mental retardation, and recurrent infection similar to LAD-I. A mutation in the GDP-fucosyl transporter leads to the absence of CD15s on leukocytes and expression of the Bombay blood phenotype (hh).¹⁵⁶ Oral fucose administration can induce the expression of CD15s, leading to improvement of the central nervous system abnormalities and decreased infection.¹⁵⁷ LAD III is characterized by a profound bleeding tendency, recurrent bacterial and fungal infections, and failure to form pus despite a marked leukocytosis.¹⁵¹⁻¹⁵³

Chronic Granulomatous Disease

CGD is a rare (1 in 1 million live births) immunodeficiency due to mutation in one of the four subunits of the *phagocyte NADPH oxidase* (PHOX) system. The function of NADPH oxidase is to transfer an electron to molecular oxygen, leading to the formation of superoxide.¹⁵⁸⁻¹⁶⁰ Approximately two thirds of cases of CGD are X-linked due to a mutation in the g91phox subunit of NADPH oxidase. Mutations of the other subunits of NADPH oxidase (p22, p47, p67) are inherited in an autosomal recessive pattern and account for the remainder of cases.

The clinical manifestations of CGD usually begin early in life (mean age of onset, 4.4 years) but may not manifest until adulthood. CGD is characterized by recurrent infections with catalase-positive organisms (*Aspergillus* spp., *S. aureus*, *B. cepacia*, and others). Residual NADPH oxidase function, which is more common in autosomal recessive forms of CGD, leads to a milder phenotype, improved survival, and delayed onset of disease.^{161,162} Pneumonias and skin infections are the most common infections, but osteomyelitis, liver abscesses, lymphadenitis, and anorectal infections are frequent as well.¹⁶³ Aerosolized exposure to organic dust can lead to fulminant fungal pneumonia termed “mulch pneumonitis” and may be the presenting manifestation of CGD, in particular the autosomal recessive forms of CGD.^{164,165} Prolonged antimicrobial or antifungal therapy, often in conjunction with systemic corticosteroids, is necessary to treat many of the infectious complications of CGD.¹⁶⁶⁻¹⁶⁸ The most common chest CT abnormalities include areas of consolidation and nodular opacities, both associated with either infection or granulomatous inflammation.¹⁶⁹ Invasive aspergillosis is the most common primary cause of death. Autoimmune diseases appear to be increased in CGD, and carriers of X-linked CGD are at increased risk for discoid lupus and photosensitivity.¹⁷⁰ As previously discussed, the diagnosis of CGD is readily made by the use of either the NBT or DHR test for phagocytic function.

Apart from infectious complications, disordered inflammation and wound healing are hallmark manifestations of the disease.¹⁶⁶ Inflammatory granuloma formation may lead to urinary or gastrointestinal tract obstruction, which are treated by systemic corticosteroids. Exuberant granulation tissue leads to disordered wound healing, including wound dehiscence following surgical procedures. The molecular basis for the disordered inflammatory response that is characteristic of CGD is complex. Comparison of global gene expression of normal and X-linked CGD neutrophils indicate that CGD neutrophils constitutively overproduce proinflammatory mediators and exhibit defective neutrophil apoptosis due to the overproduction of the anti-apoptotic protein Bcl-xl.¹⁷¹ Additionally, on apoptosis, CGD neutrophils do not properly externalize phosphatidylserine, the ligand that enables macrophages to recognize and clear apoptotic cells.¹⁷² Consequently, there is a delay in the removal of apoptotic CGD neutrophils by macrophages.¹⁷³ The deficiency in uptake of apoptotic cells may also lead to decreased production of anti-inflammatory mediators such as transforming growth factor- β , thereby contributing to the overproduction of inflammatory cytokines.¹⁶⁶ Thus, the increased production of proinflammatory mediators, reduced apoptosis, and delayed clearance of apoptotic neutrophils all likely lead to the disordered inflammatory response in CGD.

The therapy of CGD includes aggressive treatment of infection, including early surgical incision and drainage when indicated.¹⁷⁴ The prophylactic administration of trimethoprim-sulfamethoxazole markedly reduces infection, in particular infections caused by *S. aureus*.¹⁷⁵ Prophylactic itraconazole reduces serious fungal infections.¹⁷⁶ IFN- γ reduces infections and decreases mortality in both X-linked and autosomal recessive CGD, although the benefits of interferon therapy have been challenged.^{163,177} HSCT

is an increasingly preferred option for the definitive treatment of CGD.^{178,178a} Gene therapy has also been successfully performed in a small number of patients.¹⁷⁹

DISORDERS OF LEUKOCYTE SIGNALING

Defects in the IFN- γ /IL-12/IL-23 Axis

Th1-type T cells are defined by their capacity to produce high levels of cytokines (IL-2, IFN- γ , TNF- α) that are essential in the generation of a robust cellular immune response. IFN- γ , which is also produced by NK cells, interacts with a heterodimeric receptor, *IFN- γ receptor 1* (IFN- γ R1), the ligand binding receptor, and *IFN- γ receptor 2* (IFN- γ R2), which is required for downstream signaling. On ligand binding by IFN- γ R1/R2, the JAK1 and JAK2 are activated, which subsequently phosphorylate the STAT-1 protein in the cytoplasm, leading to homodimerization of STAT-1, translocation to the nucleus, and transcriptional activation of STAT-1-dependent genes. One important biologic function of IFN- γ is to induce the production of IL-12 p70 by dendritic cells and macrophages, which then feeds back in a positive loop to induce more production of IFN- γ by NK cells and T cells. IL-12 p70 is composed of two disulfide-linked subunits, p35 and p40, the latter of which also associates with the p19 subunit to form IL-23. The *IL-12 receptor* (IL-12R) is composed of two subunits, IL-12R β 1 and IL-12R β 2. IL-12R β 1 also serves as part of the heterodimeric IL-23 receptor (IL-12R β 1 and IL-23R). Thus, the IFN- γ /IL-12/IL-23 axis is intrinsically linked due to the biologic functions of IFN- γ and IL-12, the shared cytokine subunit of IL-12 and IL-23 (p40), and the common cytokine receptor subunit of IL-12R and IL-23R (IL-12R β 1).

Mutations of the genes for IFN- γ R1 or IFN- γ R2, STAT-1, IL-12 p40, IL-12R β 1, IRF-8, ISG15, and NEMO (see earlier discussion) define a group of primary immunodeficiencies known as *mendelian susceptibility to mycobacterial disease* (MSMD) (Table 92-6).¹⁸⁰⁻¹⁸⁴ Due to the marked heterogeneity in inheritance, the functional consequences of mutations in these six genes (complete or partial) leads to 13

Table 92-6 Etiologies of Mendelian Susceptibility to Mycobacterial Disease *

Gene	Inheritance	Defect	Patients with MSMD	Treatment
<i>IFNγR1</i>	AR/AD	C/P	39%	AR-C: HSCT AD-P: IFN- γ
<i>IFNγR2</i>	AR	C/P	4%	AR-C: HSCT AR-P: IFN- γ
<i>STAT1</i>	AD	P	5%	Varies depending on location of mutation
<i>IL12B</i>	AR	C	9%	IFN- γ
<i>IL12Rβ1</i>	AR	C	40%	IFN- γ
<i>NEMO (IKK-γ)</i>	X-linked	P	3%	HSCT

*Rare cases of MSMD have been found due to mutations in *ISG15* (AR) or *IRF8* (AD/AR).

AD, autosomal dominant; AR, autosomal recessive; C, complete deficiency; HSCT, hematopoietic stem cell transplantation; IFN, interferon; MSMD, Mendelian Susceptibility to Mycobacterial Disease; P, partial deficiency.

distinct genetic disorders associated with MSMD. Patients with mutations in one of these six genes are susceptible to infection with *Mycobacteria* and/or *Salmonella* but are usually resistant to infections with most other pathogens.^{180,181} This narrow susceptibility to infection in humans is somewhat surprising on the basis of the importance of Th1 responses in combating infection with a wide variety of pathogens in studies using mice.

AR complete IFN- γ R1 deficiency is characterized by the onset of infection with environmental mycobacteria, frequently rapid growers such as *Mycobacterium fortuitum* and *Salmonella*, at an early age (<3 years). Without treatment with HSCT, the disorder is fatal. However, HSCT is frequently not successful in patients with IFN- γ R1 deficiency due to preexisting high IFN- γ levels that prevent engraftment. AD partial IFN- γ R1 deficiency has a much less severe phenotype, with a mean age of onset at 13 years of age. These patients are susceptible to infection with environmental mycobacteria and may develop disseminated disease following vaccination with bacille Calmette-Guérin. Additionally, patients with partial IFN- γ R1 deficiency are uniquely predisposed to mycobacterial osteomyelitis, a complication that should trigger an evaluation for this disorder. AR complete IFN- γ R2 deficiency and AR partial IFN- γ R2 deficiency are rare, and the described phenotype to date is similar to AR complete IFN- γ R1 deficiency and AD partial IFN- γ R1 deficiency, respectively. The phenotype of patients with a *STAT1* mutation varies depending on the site of the mutation. As previously discussed, *STAT-1* homodimers mediate the transcriptional effects of IFN- γ . *STAT-1* also forms a heterodimer with *STAT-2*, which is the transcription factor formed following binding of IFN- α/β with its receptor. Consequently, some patients with mutations in *STAT2* are susceptible to viral infections and mycobacterial disease. AR complete mutations of *IL12B*, which is the only described immunodeficiency of a cytokine gene to date, result in a markedly increased susceptibility to infection with *Salmonella* in addition to mycobacterial disease. Similarly, AR complete *IL-12R β 1* deficiency, which is the most common cause of MSMD, also results in an increased susceptibility to infection with mycobacteria and *Salmonella*. Patients with deficiency in *IL-12B* and *IL-12R β 1* are also susceptible to mucocutaneous candidiasis.^{184,185} The clinical phenotype of AR complete *IL-12R β 1* deficiency is milder than complete defects in IFN- γ R1 or IFN- γ R2, and only a few patients succumb to disease. IFN- γ is useful in the treatment of patients with either *IL-12B* or *IL-12R β 1* deficiency.

DISORDERS IN INNATE IMMUNITY

MYD88 AND IRAK-4 DEFICIENCIES

Toll-like receptors (TLRs) are a family of pattern recognition receptors that are activated following microbial infection, resulting in the activation of innate immune responses. TLRs recognize conserved motifs derived from a variety of pathogenic microorganisms, including bacteria, fungi, and viruses. On ligand binding, all members of the TLR family, with the exception of TLR3, use MyD88 as a key adaptor molecule to recruit *IL-1 receptor-associated kinases* (IRAKs) leading to downstream signaling events, resulting in the

activation of the transcription factors NF- κ B and AP-1. Mutations in the genes for either MyD88 or IRAK-4 result in phenotypically similar primary immunodeficiencies. The primary immunodeficiencies caused by mutations in either *MYD88* or *IRAK4* are characterized by noninvasive and invasive infections (meningitis, septicemia, liver abscess) predominantly with *S. pneumoniae* (40% of patients) or *S. aureus* (26% of patients) and *P. aeruginosa* (18% of patients).¹⁸⁶⁻¹⁸⁸ No severe infections with viruses, fungi, or parasites have been observed, which is surprising based on the broad immunodeficiency found in mice with targeted deletion of the murine gene, *Myd88*. The onset of invasive infection is early in life, with the vast majority before age 2; the condition improves with age. All deaths in patients with IRAK-4 deficiency take place by age 8. Patients with MyD88 or IRAK-4 deficiency are frequently unable to generate a normal inflammatory response (e.g., fever, increased CRP and WBC), which contributes to the severity of the invasive infections. Standard screening tests of immune function are often normal. Peripheral blood mononuclear cells exhibit decreased inflammatory cytokine production in response to IL-1 and to all TLR agonists except agonists of TLR3. The proper management of patients with *MYD88* or *IRAK4* mutations remains to be determined, but prophylactic antibiotics and IVIG may be useful.

COMPLEMENT DEFICIENCIES

Complement has many important functions that include the modulation of inflammatory responses (e.g., vasodilation, leukocytosis, chemotaxis); clearance of immune complexes; modulation of the immune response (e.g., enhanced production of antibodies); and microbial elimination (e.g., opsonization, neutralization, microbicidal activity). Complement may also be important in the efficient removal of apoptotic cells, resulting in the presentation of self-antigens and the induction of autoimmunity. Deficiencies in components of the complement system are usually manifest by an increased propensity to infection or autoimmunity.^{1,189} There are several indications for the evaluation of the complement system, such as a strong family history of autoimmune diseases; recurrent infections caused by encapsulated bacteria; a family history of meningococcal disease; infection caused by unusual types of meningococcus (Y, W-135); age older than 9 at the time of meningococcal disease; and recurrent angioedema.

Defects in the early components of complement (C1q, C1s, C2, C4), which are inherited in an autosomal codominant manner, typically lead to an increased prevalence of autoimmune disease (primarily systemic lupus erythematosus). Redundancies in the complement pathway, including the alternative and mannose-binding lectin pathways, may explain why only a minority of patients with early complement deficiencies develops serious bacterial infections. Encapsulated bacteria (*S. pneumoniae*, *H. influenzae*) are the most common pathogens in people with recurrent infection due to deficiency in early complement components.¹⁴ C2 deficiency is the most common early component deficiency, seen in 1:10,000 to 1:28,000 live births.

The classical, alternative, and mannose-binding lectin pathways all converge at C3. For this reason, deficiencies in C3 result in more severe infections than deficiencies in other

components of complement. Patients with C3 deficiency have an increased prevalence of autoimmune disease and present in a manner similar to those with antibody deficiency.

Deficiencies in the late components of the complement pathway (C5 to C9) are also inherited in an autosomal codominant manner. Patients with late-component deficiencies are highly predisposed to infection with *N. meningitidis* and *Neisseria gonorrhoeae*. For reasons that are not clear, meningococcus serogroups W-135 and Y account for the vast majority of meningococcal meningitis infections in these patients. The prevalence of autoimmune disease is also increased, but to a much lesser extent than with deficiencies in the early components of the complement cascade. Patients with late-component deficiencies usually have the onset of infection at an older age, and many are asymptomatic well into adolescence.¹⁴

Deficiencies in components of the alternative pathway (factor D, properdin) are extremely rare and present with recurrent bacterial infections, including infections with *Neisseria* spp. Properdin deficiency is an X-linked inherited disorder in contrast to the other complement deficiencies (with the exception of hereditary angioneurotic edema), which are inherited in an autosomal codominant manner.

Therapy for complement deficiencies is primarily supportive. Individuals should be vaccinated against common bacterial pathogens associated with complement deficiency (e.g., *S. pneumoniae*, *H. influenzae*, *N. meningitidis*). Prophylactic antibiotics may be used in selected situations.

Key Points

- Patients with recurrent upper airway infections, intractable sinusitis, or more than one radiographically documented pneumonia should be evaluated for primary immune deficiency disorders (PIDDs). Abnormal screening tests for PIDDs should lead to referral to a clinical immunologist for a specific diagnosis.
- Although infection with opportunistic pathogens should always prompt a search for primary or secondary immune deficiencies, infections in patients with PIDDs are often caused by common pathogens.
- PIDDs frequently are not diagnosed in a timely manner, leading to increased morbidity and mortality. Treatment can include intravenous immune globulin or hematopoietic stem cell transplantation.
- PIDDs can be due to deficiencies in antibody production, cellular immunity, complement, or phagocytic

function. In an adult, common variable immunodeficiency is the most common diagnosis and phagocytic defects and combined immunodeficiencies are rare.

- Although immunodeficiency in adults is more commonly secondary than primary, PIDDs are seen in adults. In fact, there are more adults with PIDDs than children.
- Diffuse lung disease develops in 10% to 25% of patients with common variable immunodeficiency and has been termed granulomatous-lymphocytic interstitial lung disease.
- In patients with profound antibody deficiencies, diagnosis of microbial infection cannot rely on serologic (antibody) responses but must instead use culture or detection of microbial antigens or nucleic acids.

Other Manifestations

KIDNEY DISEASES

Pulmonary Edema
Pleural Disease
Pulmonary Calcification
Sleep Apnea
Hemodialysis-Induced Hypoxemia

INTRODUCTION

This chapter is devoted to the pulmonary complications of abdominal disease and begins with a discussion of the most relevant esophageal and bowel diseases, followed by the specific liver disorders associated with particular pulmonary complications. Finally, the respiratory consequences of diseases of the pancreas and kidney are described. The objective in each section is the same: to update the most relevant clinical, pathophysiologic, pathogenetic, and therapeutic aspects of the principal abdominal disease states and thereby assist the clinician in diagnosing and managing their sometimes complex and challenging pulmonary complications.

GASTROESOPHAGEAL AND GASTROINTESTINAL DISORDERS

GASTROESOPHAGEAL REFLUX

Gastroesophageal reflux disease (GERD) is “a condition that develops when the reflux of stomach contents causes troublesome symptoms and/or complications,” which are subclassified as esophageal and extraesophageal.¹ Among the esophageal symptoms are episodes of chest pain, which may vary from recurrent mild retrosternal “heartburn” to acute crushing substernal distress indistinguishable from the pain of angina or even acute myocardial infarction (see also Chapter 31). Among the extraesophageal symptoms, chronic cough, chronic laryngitis, and refractory asthma have attracted the most attention, but other respiratory disorders include *chronic obstructive pulmonary disease* (COPD), chronic bronchitis, pulmonary aspiration complications (aspiration pneumonia, lung abscess, bronchiectasis), and pulmonary fibrosis.

Prevalence

GERD is a common condition with a prevalence that varies from 10% to 20% in North America and Western Europe, but is lower in Asia.^{1,2} GERD is associated with cough in 10% to 40% of patients with chronic cough and with

asthma in 30% to 80% of asthmatics, depending on the patient population, diagnostic test, and number of ascertained etiologies.³ A link between GERD and chronic cough has been reported in patients of all age groups, and coexisting GERD-related chronic cough seems especially prevalent in patients with asthma, laryngitis, and bronchitis.⁴ Ambulatory monitoring studies—pH or impedance-pH—provide strong evidence linking reflux and cough.⁵ By measuring the electrical impedance of liquid boluses between pairs of electrodes along the probe, impedance-pH monitoring can detect the presence and direction of movement of boluses and correlate that with changes in pH and with symptoms. Thus, with impedance-pH monitoring, the sensitivity for the diagnosis of reflux, whether of acid or nonacid material, is increased. In the past, when the diagnosis of GERD was made by history, endoscopy, or barium esophagogram, reflux was found in approximately 10% of patients with chronic cough⁶; in contrast, when the diagnosis is made by ambulatory impedance-pH monitoring, GERD has been found in up to 40% of patients with chronic cough.⁷ The exact contribution of reflux to the patient's symptoms is often difficult to evaluate; for example, Irwin and associates⁸ reported that GERD was clinically silent in 24% of patients with difficult-to-control asthma.

The spectrum of GERD-induced respiratory disorders comprises a wide variety of complications. These disorders include chronic bronchitis, pneumonia,⁹ bronchiectasis,¹⁰ idiopathic pulmonary fibrosis,^{11,12} stable COPD and COPD exacerbations,¹³⁻¹⁶ bronchiolitis obliterans syndrome after lung transplantation,¹⁷⁻¹⁹ and nontuberculous mycobacterial lung disease, which may arise as a complication of presumed bronchiectasis and/or treatment by antacids.²⁰

Pathogenesis

Three basic GERD-associated mechanisms lead to respiratory disorders. First, gross aspiration-linked pulmonary syndromes are usually the result of free esophageal reflux with large-volume retrograde flow. Frequently, there is reduced basal lower esophageal tone and both impaired esophageal motility and clearance.²¹ Affected patients may have recurrent aspiration pneumonia, bronchiectasis, or pulmonary opacities. Endoscopic examination usually

reveals severe anatomic changes, such as visible breaks or Barrett epithelialization of the distal esophagus.

The second pathogenic mechanism is related to the microaspiration of gastric contents from the proximal (upper) esophagus. Small-volume aspirates produce an exudative mucosal reaction in the larynx and in the tracheobronchial tree. Respiratory symptoms are less obvious and range from hoarseness or chronic cough to difficult-to-control asthma. Jack and coworkers,²² using simultaneous tracheal and esophageal pH measurements in asthmatics with GERD, showed episodes of reflux that were followed by a fall in intratracheal pH; episodes with a fall in intratracheal pH resulted in a marked fall in peak expiratory flow rate that was several times greater than that observed when reflux was not followed by a change in intratracheal pH (Fig. 93-1). Accordingly, microaspiration into the bronchial tree not only takes place but also may induce an important increase in airway resistance.

Lastly, the third pathogenic mechanism linked to GERD is gastroesophageal reflux activation of a vagal reflex acting between the distal (lower) esophagus and the tracheobron-

chial tree; this reflex mechanism can be reproduced by the infusion of hydrochloric acid into the esophagus of some,²³ but not all,²⁴ patients with asthma.

The relationship between GERD and respiratory disorders is further complicated by the fact that physiologic alterations associated with asthma or cough, or with bronchodilator therapy, may themselves promote gastroesophageal reflux. Episodes of bronchospasm and cough are accompanied by an increase in the negative pressure within the thorax, and hence in the esophagus, which favors reflux; obstructive sleep apnea syndrome may act by the same mechanism to increase nocturnal reflux.²⁵ In addition, hyperinflation and "gas trapping" may flatten the diaphragm, allowing the lower esophageal sphincter to be drawn up into the thorax and impairing the antireflux barrier. Bronchodilator therapy may also promote gastroesophageal reflux. Theophylline increases gastric acid secretion and decreases lower esophageal sphincter tone. Indeed, asthmatics with gastroesophageal reflux who receive theophylline show an increase in esophageal acid exposure and reflux symptoms.²⁶ Specific β -adrenergic

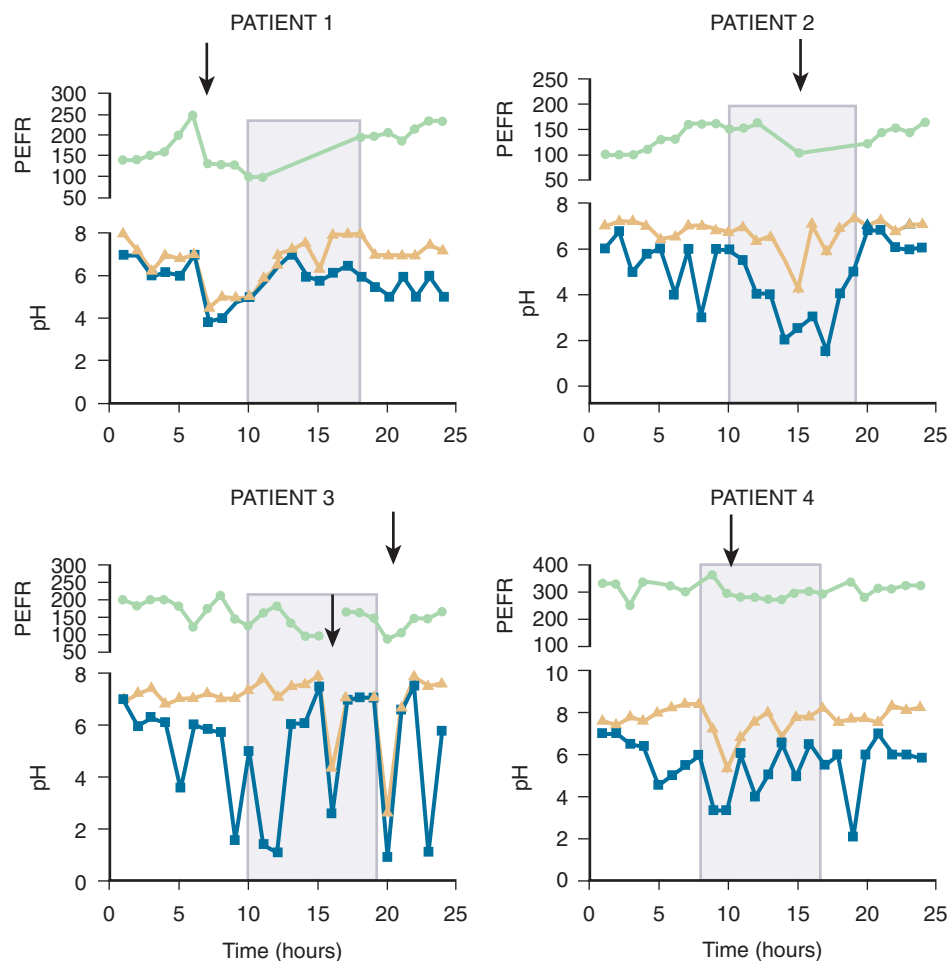

Figure 93-1 Graphs showing simultaneous esophageal (solid blue squares) and tracheal (solid beige triangles) pH measurements in four patients with both gastroesophageal reflux and asthma, along with recordings of peak expiratory flow rate (PEFR, solid pale-green circles), over a 24-hour period. In the study, there were 37 significant falls in esophageal pH suggestive of gastroesophageal reflux. Five of these episodes were followed by a fall in tracheal pH (from a mean of 7.1 to 4.1) and were associated with a significant decrease in PEFR (mean change -84 ± 16 L/min), whereas during the remaining 32 episodes of gastroesophageal reflux without tracheal aspiration, the mean change in PEFR was minimal (-8 ± 4 L/min). Gray areas show when the patient is supine. Arrows show episodes of falls in esophageal pH, tracheal pH, and PEFR. (From Jack CI, Calverley PMA, Donnelly RJ, et al: Simultaneous tracheal and oesophageal pH measurements in asthmatic patients with gastro-oesophageal reflux. *Thorax* 50:201–204, 1995.)

agents relax smooth muscle tone throughout the body thereby promoting gastroesophageal reflux. A decrease in lower esophageal sphincter pressure has been shown with β -adrenergic drugs administered orally or intravenously,²⁷ but not when these agents were given by inhalation.²⁸

Diagnosis

Guidelines provide recommendations for the diagnosis and management of GERD.^{29,30} The possibility of associated gastroesophageal reflux should be suspected in patients with refractory chronic cough or difficult-to-treat asthma. Patients should be questioned about symptoms of gastroesophageal reflux, which include heartburn, regurgitation, or dysphagia. Patients may complain of atypical symptoms, however, including substernal chest pain, hoarseness, sore throat, otalgia, hiccups, or even tooth erosion. It is important to note whether asthma or cough worsens with recumbency, after meals, or while drinking alcohol. If the clinical history is typical of gastroesophageal reflux and a trial of *proton pump inhibitor* (PPI) therapy is successful, no further diagnostic workup may be necessary.

Vocal cord dysfunction is another respiratory disorder found in patients with GERD. Vocal cord dysfunction is an intermittent paradoxical adduction of the vocal cords, mainly arising during inspiration, leading to airflow obstruction and dyspnea; patients with vocal cord dysfunction may have repetitive emergency department visits due to acute dyspnea, often mimicking exacerbations of asthma.³¹

GERD may be clinically silent in numerous patients and tests to support its diagnosis should be considered. Ambulatory reflux monitoring (pH or impedance-pH) is the test of choice to determine the presence of abnormal esophageal acid exposure, reflux frequency, and symptoms associated with reflux episodes. As mentioned, use of a multichannel intraluminal impedance-pH catheter adds impedance measurements to those of pH and provides additional data about the role of nonacid or weakly acid reflux as a cause of atypical symptoms; in addition, the catheter helps evaluate ongoing reflux in patients receiving acid-suppression therapy. Useless investigations in diagnosing GERD include barium swallows, which are restricted to evaluating putative complications; upper gastrointestinal endoscopy and esophageal biopsy, which are limited to investigating alarming symptoms and/or to excluding non-GERD causes; and esophageal manometry, which is used chiefly for preoperative evaluation.

Treatment

Treatment recommendations^{29,30} for patients with GERD include weight loss in the case of overweight/obesity, elevation of the head of the bed, and avoidance of eating within 2 to 3 hours before bedtime. PPI is the therapy of choice for symptom relief and healing of erosive esophagitis. PPIs should be initiated once a day, 30 to 60 minutes before the first meal of the day. For patients with partial responses to once-daily PPI therapy, tailored administration with adjustment of dose, its timing, and/or twice daily dosing should be considered. Treatment with PPIs must be given in sufficient doses for at least 3 months to reliably determine effectiveness. Nonresponders to PPIs should be referred for further evaluation. Maintenance PPI therapy should be administered in the lowest effective dose—including on

demand or intermittent therapy—in GERD patients who have recurrent symptoms after stopping PPIs and/or in patients with complications, such as erosive esophagitis or Barrett esophagus. When PPI treatment fails to control reflux, other treatment strategies to consider include prokinetic agents and surgical interventions. Prokinetic agents improve esophageal contractility and increase both lower esophageal sphincter pressure and gastric emptying. Surgery, such as the Nissen fundoplication, is an alternative therapy to consider when all other therapeutic approaches have failed.

Whatever the therapy, remission of GERD-induced lung symptoms is unusual, which supports the hypothesis that GERD is an aggravating rather than causative factor in most patients with extraesophageal symptoms. Indeed, there are insufficient data to provide definitive conclusions one way or the other about the role of GERD in lung symptoms. According to a Cochrane analysis,³² PPIs are not efficacious for GERD-induced cough in very young children; in adults, data are insufficient to conclude that treating GERD with PPIs is universally beneficial for GERD-induced cough. Clinicians should be aware of the possibility of spontaneous resolution of cough over time and of the placebo effect of assuming that “apparently effective” medications are beneficial. Despite a high prevalence of asymptomatic GERD among patients with poorly controlled asthma, treatment with PPIs has not been shown to improve asthma control.³³ Moreover, although many uncontrolled studies suggest that surgical procedures may improve asthmatic symptoms, conclusive studies are lacking. In patients with COPD, antireflux therapy does not have a protective effect against exacerbations.¹⁴ In idiopathic pulmonary fibrosis, no published studies demonstrate that antireflux therapy benefits the natural history of idiopathic pulmonary fibrosis. Considering that GERD is more likely only an aggravating factor for GERD-associated lung diseases, PPI can be tested in these diseases and carried on if efficacious.

INFLAMMATORY BOWEL DISEASE

Extraintestinal complications of *inflammatory bowel disease* (IBD) have been described in virtually all organ systems; but, surprisingly, disease in the lungs appears “much less frequently” than manifestations in other organs.³⁴ We say “surprisingly” because the gut and lungs share a common embryologic origin, and thus might possess similar vulnerability to immunologically mediated comorbidities. Pulmonary complications arise more commonly with ulcerative colitis than with Crohn disease; respiratory involvement may develop at any age, and some conditions (e.g., airway disease) appear more often in women than in men.³⁴ In most cases, respiratory symptoms develop after the diagnosis of IBD has been made, frequently several years afterward. Nonetheless, respiratory symptoms can antedate or be concomitant with those of the bowel disease.³⁵ Even in patients without symptoms, there may be impaired pulmonary function, such as a decrease in *diffusing capacity for carbon monoxide* (DL_{CO}) and forced expiratory volume in 1 second, and an increase in residual volume and bronchial hyperresponsiveness. Reviews³⁴⁻³⁶ of published cases have confirmed and extended earlier observations about the

 Chronic thromboembolic pulmonary hypertension

noniatrogenic pulmonary complications of IBD, which can be classified as shown in Table 93-1.

Most intrinsic (non-drug-related) pulmonary complications involve the airways—anywhere from the larynx to the bronchioles—and may take the form of epiglottitis, tracheal stenosis, bronchiectasis, chronic bronchitis, or bronchiolitis. Endoscopic examination shows marked erythema, swelling of the mucosa, and deformation of the airway lumen. Biopsy specimens have revealed mucosal ulceration, thickening of the basement membrane, and marked infiltration by neutrophils and plasma cells.^{34,35} In some cases, the inflammatory process in the subglottic area can take the form of pseudotumoral lesions, with the potential of producing life-threatening acute upper airway obstruction requiring aggressive airway management.^{35,37} This panoply of discrete airway pathology has been enriched by the addition of asthma, which proved to be the most common pulmonary comorbidity of both ulcerative colitis and Crohn disease identified in a large cohort. The association between IBD and asthma supports the belief that patients suffering from one autoimmune condition are more likely than the general population to have a second immune-mediated disorder, which may result from shared susceptibility genes.³⁸

Another major category of pulmonary complications of IBD is the group of parenchymal disorders, including interstitial lung diseases, such as cryptogenic organizing pneumonia, sarcoidosis, interstitial fibrosis, and pulmonary infiltration with eosinophilia. Pulmonary function test results in patients with IBD, even when asymptomatic and with normal chest radiographs, may reveal a variety of abnormalities. Probably the most common is an obstructive ventilatory defect, as described earlier, but pulmonary restriction is also well described. A reduction in DL_{CO} during the active phases of IBD has been reported,³⁹ which also

suggests that subclinical pulmonary parenchymal involvement may be more prevalent than previously suspected. Furthermore, bronchoalveolar lavage examination in patients with Crohn disease—who did not have clinical evidence of pulmonary involvement—has revealed the presence of a lymphocytic alveolitis, chiefly owing to an increase of CD4-positive T lymphocytes.³⁸

Other pulmonary lesions include necrobiotic nodules, corresponding histologically to aggregates of neutrophils with areas of necrosis, which have been reported in a few patients.³⁵ Serositis affecting the pleura or the pericardium, or both, has been reported in a small number of cases, especially during periods of increased disease activity. Finally, colobronchial fistulas have been reported in some cases of Crohn disease, the majority of them presenting with left lower lobe pneumonia.³⁴ Involvement of the esophagus is rare in Crohn disease, but a few cases of bronchoesophageal fistula associated with esophageal Crohn disease have been reported.³⁴ Although conservative management has been tried, most patients with fistulas require surgical treatment.

Pulmonary thromboembolic events and chronic thromboembolic pulmonary hypertension are more frequent in patients with IBD, even in those who are asymptomatic, than in control subjects.^{36,40-42} The study by Grainge and colleagues indicates that patients with stable IBD have a higher risk of venous thromboembolism than controls, (*hazard ratio* [HR], 3.4); in addition, those patients with an IBD flare have an even higher incidence of thromboembolism (HR, 8.4).⁴³ Because deep vein thrombosis and pulmonary embolism may be clinically silent, an early diagnosis of thromboembolism can be challenging, and the duration of systemic anticoagulation must take into account the individual risk of intestinal bleeding.⁴⁴

In addition, drugs are a frequent cause of pulmonary manifestations in patients with IBD.³⁴ Antiinflammatory drugs, often the first step in the treatment of IBD, consist of aminosalicylates (sulfasalazine, mesalamine) and glucocorticosteroids. Immune system suppressors (azathioprine, methotrexate) and *tumor necrosis factor-α* (anti-TNF-α) inhibitors serve to maintain remission. Because most of these medications induce respiratory side effects, consequences of therapy must be considered in the differential diagnosis of new-onset lung disease; offending medications must be recognized and discontinued to prevent a potentially fatal outcome. The spectrum of medication-induced respiratory manifestations includes eosinophilic and granulomatous pneumonitis, interstitial lung disease, pulmonary fibrosis, and a heightened susceptibility to infections.^{45,46} Azathioprine increases the risk of both infection and disease by viruses, glucocorticosteroids by fungi, and TNF-α inhibitors by intracellular microorganisms (mycobacteria, fungi).

The majority of patients with pulmonary disorders associated with IBD are treated with glucocorticosteroids, either by inhalation or by mouth, which usually results in rapid control of symptoms,^{35,47} especially in those patients who do not have severe structural impairment (e.g., bronchiectasis). Lung transplantation has been performed in some patients with severe respiratory compromise associated with IBD.³⁵

HEPATIC DISEASES

PLEURAL EFFUSION

Pleural effusion develops in 5% to 10% of patients with cirrhosis of the liver and is traditionally referred to as *hepatic hydrothorax* in the absence of coexisting cardiopulmonary disease (see Chapter 79). Unless the pleural fluid is complicated by infection, hepatic hydrothoraces are transudates and are most commonly located in the right hemithorax. Effusions may also be left-sided or bilateral, and may or may not be associated with concurrent ascites. The effusion is usually mild to moderate in size and asymptomatic, but in some cases it can be massive and provoke shortness of breath. The mechanism is related to the presence of anatomic communications—usually small diaphragmatic defects—and to the prevailing pressure gradient between the abdominal and pleural cavities that facilitates movement of ascitic fluid into the chest. The presence of pleural fluid disturbs lung mechanics, resulting in decreased lung volumes and pulmonary compliance, and pulmonary gas-exchange abnormalities.⁴⁸

The clinical management of pleural effusion associated with liver disease is often difficult. Repeated thoracenteses have only transitory effects, and thoracostomy tube drainage may result in substantial protein loss. Transjugular intrahepatic portosystemic shunting decreases portal hypertension and, in turn, reduces the size of both the ascites and hydrothorax; transjugular intrahepatic portosystemic shunting is often beneficial, at least in the short term, but long-term outcome depends on the severity of the underlying liver dysfunction.⁴⁹ If the patient is not a candidate for transjugular intrahepatic portosystemic shunting, other approaches, including video-assisted thoracoscopic surgery to repair diaphragmatic defects and/or induce a pleurodesis, should also be considered.⁵⁰

PULMONARY FUNCTION DISTURBANCES

The most common lung function abnormality in patients with end-stage hepatic disease is a decreased DL_{CO} ; likewise, both obstructive and restrictive ventilatory defects have been observed.⁵¹ The coexistence of massive ascites can decrease lung compliance, increase pleural pressure, and reduce diaphragmatic motility. Together, these pathophysiologic alterations restrict ventilatory capacity and reduce the efficiency of gas exchange, causing increased alveolar-arterial PO_2 difference values with or without clinically evident hypoxemia.⁵²

HEPATOPULMONARY SYNDROME

Severe hypoxemia (arterial $PO_2 < 60$ mm Hg) is uncommon in patients with uncomplicated chronic hepatic disease and, when present in patients without coexisting cardiopulmonary disease, should strongly suggest *hepatopulmonary syndrome* (HPS). Because patients with advanced liver disorders characteristically hyperventilate and are hypocapnic, measurement of the alveolar-arterial PO_2 difference becomes more sensitive than arterial PO_2 alone to detect gas-exchange disturbances in HPS.⁵³

Table 93-2 Grading of Severity of Hepatopulmonary Syndrome*

Stage	Alveolar-Arterial Oxygen Difference	Arterial Partial Pressure of Oxygen
Mild	≥ 15 mm Hg	≥ 80 mm Hg
Moderate	≥ 15 mm Hg	< 80 to ≥ 60 mm Hg
Severe	≥ 15 mm Hg	< 60 to ≥ 50 mm Hg
Very severe	≥ 15 mm Hg	< 50 (< 300 mm Hg [40 kPa] on 100% oxygen breathing)

*All with positive contrast-enhanced echocardiography, breathing room air at rest and at sea level.

HPS is rigorously defined as a syndrome characterized by a clinical triad: (1) advanced chronic liver disease; (2) arterial oxygenation defect, which ultimately leads to severe arterial hypoxemia; and (3) widespread pulmonary vascular dilations.^{54,55} The pulmonary gas-exchange disturbance is characterized by arterial oxygen desaturation that may be mild, moderate, severe, or extremely severe (Table 93-2). There is an increased alveolar-arterial PO_2 difference, commonly associated with hypocapnia and respiratory alkalosis. At sea level, while breathing ambient air, resting alveolar-arterial PO_2 difference values at or above 15 mm Hg can be considered abnormal for most adults; for those older than 64 years, an alveolar-arterial PO_2 difference equal to or above 20 mm Hg can be considered abnormal. Although HPS is prevalent in most kinds of common chronic liver diseases, it may also be seen in other unusual liver disorders such as Budd-Chiari syndrome.^{56,57}

The most conspicuous pathologic finding is pronounced vascular dilation of all peripheral branches of the pulmonary vasculature, at both the precapillary and capillary levels of the lung (15 to 150 μ m in diameter), near the gas-exchange area in an otherwise intact pulmonary parenchyma.

Pathogenesis

The precise mechanism underlying HPS remains uncertain despite numerous investigations. Whether the mechanism of hemodynamic disturbances is related to a failure of metabolism, to insufficient production of one or more circulating vasoactive substances by the injured liver, or to altered clearance of putative vasodilator molecules produced by endothelial cells⁵⁸ remains unknown.

Nitric oxide (NO), a ubiquitous biologic agent considered to be a “fine-tuner” of vascular tone, has been presumed to be a pivotal signaling molecule of importance in the pathobiology of HPS.^{54,59} Persistent induction of *NO synthase* (NOS) could account for the hyperkinetic circulatory hallmarks of HPS.⁵⁹ Both a constitutive isoform of NOS, expressed in endothelial cells (eNOS, or type III NOS),⁶⁰ and the inducible NOS (iNOS, or type II NOS), expressed in target tissues such as human bronchial epithelial cells after exposure to proinflammatory cytokines,⁶¹ have been implicated in experimental models of HPS. In keeping with this contention, increased levels of exhaled NO have been observed in patients with advanced hepatic cirrhosis and in those with HPS.⁶² However, after interventions designed to improve

HPS, changes in measurements of exhaled NO have been discrepant.⁶³⁻⁶⁵

In patients with liver cirrhosis, the close correlations between exhaled NO concentration and the Child-Pugh score and levels of alkaline phosphatase, bilirubin, aspartate and alanine aminotransferases, and albumin suggest that NO formation in the lung may be triggered by stimulating factors normally inactivated by the liver.⁶³ More recent work suggests that endothelin-1 and TNF- α can both interact in the development of experimental HPS.^{54,66,67} Carboxyhemoglobin, a known vasodilator and breakdown product of hemoglobin, has also been associated with abnormal gas parameters in HPS, suggesting a possible contributory role.⁶⁸

Clinically, most patients with HPS are cyanotic, show conspicuous finger clubbing, may complain of shortness of breath and platypnea (increased dyspnea after assuming the upright position and relieved by recumbency), and have a hyperkinetic circulation. The majority of patients exhibit the typical clinical and functional stigmata of advanced liver failure, such as portal hypertension; in a few cases, severe pulmonary abnormalities may antedate those of hepatic dysfunction. The presence of abundant cutaneous spider angiomas has been postulated as a clinical marker of the severity of the systemic and pulmonary circulatory and gas-exchange abnormalities observed in HPS.⁶⁹ The severity of HPS generally correlates with the severity of hepatic failure, as shown by higher Child-Pugh scores and hepatic venous pressure gradients,⁷⁰ as well as scores from the Model for End-Stage Liver Disease.⁷¹ In approximately one third of patients with HPS, the syndrome can coexist with other chronic respiratory comorbidities such as COPD or pulmonary fibrosis. Nevertheless, the prevailing clinical and functional pulmonary features in patients with such comorbidities are generally those of HPS.⁷²

Diagnosis

Systemic hypotension, a normal or low *pulmonary artery pressure* (PPA), an inordinately high cardiac output, and a reduced pulmonary vascular resistance are the hemodynamic hallmarks of HPS. When the constellation of hypoxemia, normal or low PPA, spider nevi, and finger clubbing is observed in a patient with advanced liver disease, the diagnosis of HPS is likely.

The diagnostic criteria for HPS are as follows⁵⁴: presence of liver disease; gas-exchange abnormalities, more specifically an increased alveolar-arterial PO_2 difference (>15 mm Hg), with or without concomitant arterial hypoxemia (arterial $PO_2 < 80$ mm Hg); and a positive contrast-enhanced echocardiogram or an abnormal intravenous radiolabeled perfusion lung scan, or both. Additional features that can be useful for further establishing the diagnosis of HPS include a decreased DL_{CO} , dyspnea with or without platypnea and orthodeoxia (i.e., arterial hypoxemia that worsens by at least 5% or 4 mm Hg when the patient is upright vs. recumbent), and a hyperkinetic circulatory state with normal or low PPA. Although thoracic computed tomography scanning appears to be nonspecific, it may be used to exclude coexistent respiratory comorbidities.⁵⁴

Two-dimensional contrast-enhanced echocardiography appears to be the most sensitive and accurate noninvasive diagnostic procedure to identify right-to-left shunts by finding microbubbles of air in the left heart cavities within 3 to 6 beats of their visualization in the right-sided chambers⁵⁴ (Fig. 93-2) (see Video 61-1). Normally, echogenicity in the left chambers is not detected because the intravenously injected microbubbles (60 to 90 μ m in diameter) are trapped in the pulmonary capillaries (8 to 15 μ m in diameter). Contrast-enhanced echocardiography cannot distinguish among the different forms of pulmonary vascular deformities (i.e., precapillary, capillary, and pleural

Figure 93-2 Contrast-enhanced echocardiograms in a patient with hepatopulmonary syndrome. Left, Normal four-chamber view (LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle). Center, Injected microbubbles appear in the RV (arrow). Right, Within five beats, microbubbles appear in the LV (arrow). The demonstration of microbubbles in the left cardiac chambers is highly suggestive of the presence of intrapulmonary vascular dilations, or, alternatively, of anatomic arteriovenous malformations. (See also Video 61-1.) (Courtesy Dr. C. Paré, Hospital Clínic, Universitat de Barcelona, Barcelona.)

dilations vs. direct arteriovenous communications), but it can clearly differentiate them from intracardiac malformations, such as a patent foramen ovale, in which the microbubbles appear in the left heart almost simultaneously with their appearance in the right. Alternatively, the demonstration of technetium-99m-macroaggregated albumin activity over extrapulmonary organs (e.g., liver, spleen, kidneys, and brain) strongly suggests the presence of right-to-left shunting, because under normal conditions the albumin macroaggregates (20 to 60 μm in diameter) are completely trapped in the pulmonary capillary bed.⁵⁴ This test does not distinguish between intrapulmonary and intracardiac shunting but can serve to estimate the severity of the shunt.

The prevalence of HPS ranges between 5% and 32%.⁵⁴ Using contrast-enhanced echocardiography—the “gold standard” for identifying intrapulmonary vascular dilations—the prevalence of a positive echocardiography test in patients with chronic liver disease is approximately 20%.^{57,73} However, patients with a positive contrast-enhanced echocardiogram without coexisting gas-exchange disturbances, are considered to have a *forme fruste* of HPS whose natural history is not yet known.^{73,74}

Although data describing the natural history of HPS are scant, it appears that patients with HPS not undergoing liver transplantation worsen progressively and have an adverse outcome, with median survival of 41 months following the diagnosis of HPS.⁵⁴ In a prospective study, HPS was an independent risk factor for poor prognosis in patients with cirrhosis; those with HPS had a significantly shorter median survival (approximately 11 months) than those without HPS (41 months), even after adjusting for differences in liver disease.⁷⁵

Gas-Exchange Abnormalities

When HPS is mild to moderate, the predominant mechanism of hypoxemia is ventilation-perfusion inequality, essentially due to the presence of areas in which ventilation is preserved but perfusion is profoundly increased. In contrast, when HPS is severe, increased intrapulmonary shunt develops and worsens along with coexisting ventilation-perfusion imbalance, and constitutes the primary abnormality. Collectively, with increasing severity of the liver dysfunction, there is greater systemic and pulmonary dilation, a lower hypoxic pulmonary vascular response, and a greater degree of ventilation-perfusion inequality, including increased intrapulmonary shunt.^{54,76} A “diffusion-perfusion defect” has also been postulated to explain an increased diffusion gradient for oxygen in dilated pulmonary capillaries (Fig. 93-3). The contention is that pulmonary vascular dilation causes inadequate diffusion of oxygen to the center of the enlarged capillary. Moreover, the coexistence of a hyperkinetic state and the resulting shorter transit time of red blood cells would exaggerate this diffusion-induced gas-exchange disturbance.⁷⁷

Treatment

Many therapeutic agents have been tried in HPS, including bismesylate almitrine, long-term oxygen therapy, methylene blue, and propranolol, with disappointing results.⁷⁷ The only successful treatment thus far is liver transplantation. In theory, replacement of the damaged organ should prevent all HPS-induced abnormalities, except for persistent

low DL_{CO} , whose mechanism remains unclear.⁵⁴ As might be expected, the worse the hypoxemia before transplantation, the longer it takes to resolve after surgery.⁷⁸ In the largest reported single-institution study thus far, 5-year survival after liver transplantation for HPS was 76% and did not differ from the survival rate after transplantation in patients without HPS.⁷⁹

Youth, a good arterial PO_2 response to 100% oxygen breathing, and less presurgical hypoxemia are all factors that seem to predict a favorable response to liver transplantation.⁸⁰ Collectively, these elements may indicate a more reactive pulmonary vasculature and less profound intrapulmonary shunt. However, a more recent study of patients with HPS undergoing liver transplantation indicated that survival was not correlated with arterial PO_2 at the time of diagnosing HPS.⁸¹

PORTOPULMONARY HYPERTENSION

Pulmonary arterial hypertension (PAH) associated with portal hypertension—also known as *portopulmonary hypertension* (POPH)—is another mysterious pulmonary vascular disorder that appears to be associated with chronic hepatic disease.^{55,80,82} Because both the diagnosis and the outcome of POPH, particularly in relation to the therapeutic benefits of liver transplantation, appear to be substantially different from those of HPS, it is important to highlight the distinctions between the two disorders. POPH is defined by the following triad of hemodynamic abnormalities in a patient with portal hypertension: (1) mean PPA exceeding 25 mm Hg at rest; (2) mean pulmonary artery wedge pressure less than 15 mm Hg; (3) pulmonary vascular resistance greater than $240 \text{ dynes} \cdot \text{sec}^{-1} \cdot \text{cm}^{-5}$ (normal, less than $130 \text{ dynes} \cdot \text{sec}^{-1} \cdot \text{cm}^{-5}$).⁸²

Various studies have estimated the prevalence of portopulmonary hypertension in those evaluated for liver transplantation as between 5% and 6%.⁸³ Furthermore, findings from a large cooperative trial of 536 patients with portal hypertension established that female gender and associated autoimmune hepatitis conferred increased risk for development of POPH, whereas hepatitis C was associated with decreased risk.⁸³

In classic retrospective postmortem studies, the prevalence of histopathologic evidence of PAH in patients with liver cirrhosis or POPH (or both) ranged between 0.25% and 0.73%.⁸⁴ In a case-control study conducted by the International Primary Hypertension Study Group, the incidence of primary (or idiopathic) PAH was found in 7.3% of patients with cirrhosis, 3.1% of those with human immunodeficiency virus infection, and none of the controls.⁸⁵ According to these and subsequent observations, POPH has been classified as a category of PAH with hemodynamic criteria consistent with the standard classification and definition of PAH, as discussed in Chapter 58 (see Table 58-1).^{55,86,87}

From a histopathologic viewpoint, the vascular lesions in POPH are indistinguishable from those identified in idiopathic (primary) PAH (see Chapter 58), namely intimal thickening, smooth muscle proliferation, plexogenic pulmonary arteriopathy, and in situ thrombosis,⁸⁸ all of which—plus vasoconstriction—contribute to the greatly increased pulmonary vascular resistance.⁸⁹ Chemla and colleagues⁹⁰ postulated that the portosystemic shunting of vasoactive

Figure 93-3 Mechanisms of arterial hypoxemia in hepatopulmonary syndrome in a two-compartment gas exchange model. **A**, In the homogeneous lung of a healthy individual, with uniform alveolar ventilation and pulmonary blood flow, the capillary ranges between 8 and 15 μm in diameter and oxygen diffuses properly into the capillary while ventilation-perfusion is well balanced. **B**, In hepatopulmonary syndrome, where many capillaries are dilated and blood flow is nonuniform, alveolar ventilation-to-pulmonary perfusion mismatch emerges as the predominant mechanism at any clinical stage, either with or without the presence of intrapulmonary shunt and coexistent with oxygen diffusion limitation into the center of the dilated capillaries in the most advanced stages. (From Rodriguez-Roisin R, Krowka MJ: Hepatopulmonary syndrome—a liver-induced lung vascular disorder. *N Engl J Med* 358:2378–2387, 2008.)

agents such as thromboxanes, serotonin, bradykinin, and neuropeptide Y, which are normally metabolized by the healthy liver, may result in pulmonary arterial vasoconstriction; an attractive alternative hypothesis is that pulmonary endothelial dysfunction leads to a decreased production of the endogenous vasodilator NO.

The most common symptom of POPH is shortness of breath on exertion; patients may also experience chest pain, syncope, and hemoptysis.⁹¹ Radiographically, both an enlarged cardiac silhouette and a pulmonary artery prominence are noted in approximately one half to two thirds of patients with POPH.^{83,91} Overall, maximal airflow rates and lung volumes are normal or nearly normal, whereas DL_{CO} , arterial PO_2 , and alveolar-arterial PO_2 difference may be reduced, although less so than in HPS.⁸³ Compared with patients with idiopathic PAH, patients with POPH have a lower mean PPA and a higher cardiac index and mixed venous oxygen saturation.⁸⁹

Transthoracic echocardiography is now done routinely in patients being considered for liver transplantation because the presence of POPH affects the outcome of surgery. Characteristic echocardiographic findings of idiopathic PAH in the setting of portal hypertension suggest,

but do not prove, POPH. Right heart catheterization is needed to confirm the diagnosis. Until recently, it was believed that median survival in POPH was extremely poor; new information, however, indicates overall survival rates at 1 and 3 years of 88% and 75%, similar to that in patients with idiopathic PAH.^{86,88}

Treatment for POPH, however, remains challenging because there are no randomized controlled studies for guidance: available agents include epoprostenol, iloprost, sildenafil, and bosentan.⁹² In a retrospective study, the safety and efficacy of inhaled iloprost and bosentan were assessed in 31 patients with POPH for up to 3 years; although both agents were safe with regard to liver function, bosentan proved to be better than iloprost in improving exercise capacity, hemodynamics, and—of note—survival rates.⁹³ Prospective trials are clearly needed to provide further guidance.

PRIMARY BILIARY CIRRHOSIS

Primary biliary cirrhosis, an autoimmune disease, is characterized by a chronic, cholestatic, granulomatous, and destructive process that involves the intrahepatic bile

ducts.⁹⁴ When severe, these processes result in cholestasis, cirrhosis, and liver failure. The autoimmune basis is reflected in the presence of several immunologic alterations, such as depressed T-suppressor cell function, hypergammaglobulinemia, and the presence of antimitochondrial antibodies. Connective tissue diseases such as the sicca complex, Sjögren syndrome, and scleroderma are frequently associated with primary biliary cirrhosis,^{95,96} which also has an association with POPH.⁸³ Several respiratory abnormalities have been associated with primary biliary cirrhosis: interstitial lung disorders, such as lymphocytic interstitial pneumonitis and fibrosing alveolitis; subclinical intrapulmonary granulomas that mimic sarcoidosis⁹⁷; increased numbers of CD4⁺ lymphocytes in the bronchoalveolar lavage fluid; and obstructive airway disease, such as bronchiectasis.⁹⁸ Occasionally, the pulmonary manifestations precede the liver involvement.⁹⁹ In addition, thoracic wall deformities secondary to osteopenic vertebral complications induced by abnormal vitamin D metabolism related to poor absorption of fat-soluble vitamins can be also observed.⁹⁸ A reduced DL_{CO}, with or without ventilatory defects, is one of the functional hallmarks of the disease, particularly when a connective tissue disorder coexists.⁹⁹⁻¹⁰¹

CHRONIC ACTIVE HEPATITIS

Chronic active hepatitis, an increasingly frequent liver disease that is characterized by diffuse parenchymal inflammation and hepatic cell necrosis, may be caused by viral hepatitis (most commonly hepatitis C virus), autoimmune disorders, and drug-related liver injury. Pulmonary fibrosis and lymphoid interstitial pneumonitis have been reported but are rare.^{100,102} After years of smoldering inflammation, which is often asymptomatic, chronic active hepatitis can lead to cirrhosis and liver failure, which has been associated with HPS.⁹⁸ Patients with chronic hepatitis C virus infection and coexistent COPD may demonstrate an accelerated annual decline in forced expiratory volume in 1 second.¹⁰³

SCLEROSING CHOLANGITIS

Sclerosing cholangitis is an unusual disease that results from chronic inflammation affecting both intrahepatic and extrahepatic bile ducts. It has been linked with inflammatory obstructive airway diseases such as bronchiectasis; however, the relationship remains unproven because ulcerative colitis, a frequent clinical accompaniment, has also been associated with the same respiratory complications.¹⁰⁴

ALPHA₁-ANTITRYPSIN DEFICIENCY

The discovery that certain patients with COPD had low levels of circulating alpha₁-antitrypsin led to the current protease-antiprotease theory of the pathogenesis of pulmonary emphysema (see Chapter 43 for complete discussion). This hereditary disorder is nearly always associated with the homozygous PiZZ phenotype. Genetically predisposed infants often present with hepatomegaly or hepatosplenomegaly and evidence of cholestasis. Most children with alpha₁-antitrypsin-induced liver disease recover, but cirrho-

sis develops in about 15%, presumably from toxic effects of the mutant antitrypsin protein retained in the endoplasmic reticulum of hepatocytes¹⁰⁵; HPS has been reported as a complication of this form of cirrhosis.¹⁰⁶ COPD is the most common pulmonary complication. COPD is unrelated to the presence of liver disease, develops in adults, and is characterized by panacinar emphysema, especially in the lower lung zones, and bronchial abnormalities, including bronchiectasis.⁹⁸

PANCREATITIS

Pancreatitis may be acute or chronic and has two main origins: gallstone migration and chronic alcoholism. But more and more causes of pancreatitis have been identified and a classification of etiologies has been proposed according to the following acronym TIGAR-O: toxic-metabolic, idiopathic, genetic, autoimmune, recurrent, and obstructive.¹⁰⁷ Most episodes of acute pancreatitis are mild, but can be severe in about 20% of patients, of whom 15% to 25% die.¹⁰⁸ Pulmonary complications are frequent and account for significant mortality; intrathoracic complications contribute to death in 22% to 29% of patients who succumb from fatal pancreatitis, and arterial hypoxemia (PO₂ < 60 mm Hg) is a major factor affecting survival.¹⁰⁹ Besides hypoxemia, pleural effusion and *acute respiratory distress syndrome* (ARDS) influence the outcome of respiratory failure in acute pancreatitis.^{110,111}

RESPIRATORY FAILURE

Gas exchange disturbances, ranging from mild hypoxemia to ARDS may arise during episodes of acute pancreatitis. Arterial hypoxemia and normal results on chest radiograph is a frequent finding of acute pancreatitis in its early stages.¹¹² Initially, arterial hypoxemia may be asymptomatic and mild, but patients who present with hypoxemia during an episode of acute pancreatitis should be closely monitored for worsening respiratory failure; for example, Ranson and associates¹¹³ reported that, of 67% of patients who had an initial arterial PO₂ less than 66 mm Hg in whom clinical respiratory symptoms developed afterward, 39% died.¹¹³

The mechanisms of arterial hypoxemia in the setting of a normal chest radiograph finding during acute pancreatitis remain poorly understood. Murphy and associates¹¹⁴ showed that hypoxemia in these patients was caused by an increase in the right-to-left shunt fraction, which usually improved after recovery. No changes were seen in expiratory flow rates, lung volumes, or closing capacity, compared with measurements performed after recovery. These authors suggested that hypoxemia in the absence of radiologic abnormalities may be related to changes in pulmonary vascular permeability, similar but milder than that described in ARDS.¹¹⁴ De Troyer and associates¹¹⁵ measured a transient reduction of DL_{CO}, and suggested that increased capillary permeability and impaired DL_{CO} result from factors released by the injured pancreas. In addition, Greenberg and coworkers¹¹⁶ demonstrated a reduction in the oxygen affinity of hemoglobin related to the increase in circulating fatty acids.

ARDS developed in about 15% to 20% of patients with severe acute pancreatitis, with a reported mortality rate of 56%.¹¹⁷ The incidence of ARDS is higher in patients with hemorrhagic than with nonhemorrhagic pancreatitis.^{118,119} Respiratory symptoms typically appear 2 to 7 days after the onset of the acute episode, when the chest radiograph usually shows signs of pulmonary vascular congestion that progresses to bilateral diffuse opacities. Severe hypoxemia is usually associated with marked hypocapnia. Pathologic findings reveal evidence of acute lung injury indistinguishable from that observed in ARDS attributable to other causes.¹¹⁸

Lung injury associated with acute pancreatitis may result from a direct toxic effect of pancreatic products, from secondary release of inflammatory mediators, or from both. Several pancreatic products have the potential to induce lung injury. Phospholipase A₂ binds to pulmonary capillaries and has the ability to induce the enzymatic degradation of the phospholipid components of surfactant, thereby promoting alveolar collapse and increased vascular permeability.^{108,110} Free fatty acids from triglyceride degradation by circulating lipase may induce alveolar edema and hemorrhage.¹¹⁰ Pancreatic enzymes can induce lung injury and increase vascular permeability.¹²⁰ In addition to the direct effect of pancreatic products, sequestration of neutrophilic leukocytes within the alveolar and interstitial spaces is believed to play an important role in inducing lung injury and increasing pulmonary vascular permeability¹⁰⁸; moreover, mediators released during pancreatic injury, such as reactive oxygen species,¹²¹ adhesion molecules, platelet-activating factor,^{110,122} and many cytokines, may contribute to associated pulmonary vascular permeability.¹¹⁰

Because initially chest radiographs often appear normal, arterial hypoxemia may be clinically unsuspected and undetected but profound; therefore a high index of suspicion should be present for respiratory impairment in patients with acute pancreatitis, and arterial blood gases should be measured periodically during the initial 48 to 72 hours following hospitalization.¹²³ When hypoxemia develops, patients should receive supplemental oxygen to raise the arterial Po₂ above 70 mm Hg. Treatment of pancreatitis-associated lung injury is essentially supportive and does not differ from that for other forms of lung injury (see Chapter 43). Key measures include cardiovascular support and lung-protective ventilation.¹⁰⁸

Additional treatment includes suppression of the secretory function of the pancreas by elimination of oral intake, use of nasogastric suction, and inhibition of gastric acid secretion with histamine₂ blockers. Studies suggest that octreotide, a potent inhibitor of exocrine pancreatic secretion, may decrease both mortality rates and the incidence of ARDS among patients with severe acute pancreatitis.^{124,125} Nevertheless, controlled randomized trials of the effectiveness of octreotide in the prevention and treatment of pancreatitis-associated ARDS are needed.¹²⁵

PLEURAL EFFUSION

Pleural effusions may be associated with both acute and chronic pancreatitis (see Chapter 79). In acute pancreatitis, pleural effusion is a relatively frequent finding, being present

in about 20%¹²⁶ to 50% of patients.¹¹¹ In most cases these effusions are of small size; the majority (68%) are left sided, 22% are bilateral, and only 10% are right sided.¹¹⁰

Various pathogenic mechanisms have been proposed to explain the development of pleural effusions associated with acute pancreatitis¹²⁶: (1) increased fluid leak caused by pancreatic enzymes that may diffuse from the peritoneal side to the thoracic side of the diaphragm, (2) impaired lymphatic drainage of pleural exudate caused by obstruction of lymphatic vessels by the high enzymatic content of the pleural fluid, and (3) increased permeability of diaphragmatic capillaries caused by the inflammatory process in the adjacent pancreas.

In patients with pleural effusion associated with acute pancreatitis, symptoms are primarily abdominal (pain, nausea, and vomiting); occasionally, respiratory symptoms (pleuritic pain and dyspnea) may be present. The diagnosis is established by demonstrating an elevated amylase concentration in pleural fluid, a concentration that may be up to 30 times higher than that in plasma.¹⁰⁸ The pleural fluid usually is an exudate, which is sometimes bloody, and has a high concentration of both protein and lactic acid dehydrogenase; the differential white blood cell count reveals a predominance of polymorphonuclear cells.

Pleural effusions associated with acute pancreatitis usually are self-limited and resolve when the pancreatic inflammation subsides without requiring therapeutic drainage. Therefore, if the pleural effusion does not resolve within 2 weeks after treatment for the pancreatic disease, the possibility of a pancreatic abscess or a pseudocyst should be considered.

Chronic pleural effusions are usually associated with chronic relapsing pancreatitis and pancreatic pseudocyst. In most cases, a history of alcohol abuse is present.¹²⁷ Chronic effusions are large, may occupy the entire hemithorax, and reaccumulate rapidly after thoracentesis.

The typical mechanism of a chronic effusion is a pancreaticopleural fistula, a direct communication between the pancreas and the pleural space. In chronic pancreatitis, the pancreatic duct may rupture because of high internal pressure. Once the duct is disrupted, pancreatic secretions can flow into the retroperitoneum, then into the mediastinum through the esophageal or aortic hiatuses, and then into the pleural space (Fig. 93-4, see also Fig. 79-9). Occasionally, a direct communication may develop between a pancreatic pseudocyst and the pleural cavity through the left hemidiaphragmatic dome.¹²⁷

Patients with chronic pancreatic effusions usually complain of respiratory symptoms such as chest pain and shortness of breath. Surprisingly, abdominal symptoms may be absent, probably because the pancreaticopleural communication decompresses the pseudocyst.¹²⁶ Therefore the diagnosis of a chronic pancreatic pleural effusion should be suspected in any patient with a large pleural effusion who appears to be chronically ill or has a history of pancreatic disease or alcohol abuse.¹²⁸ The diagnosis is established by the demonstration of a high concentration of amylase in the pleural fluid; in the setting of a pancreaticopleural fistula, amylase concentrations can be exceedingly high, often greater than 10,000 U/L. Ultrasonography and computed tomographic scanning of the chest and abdomen

Figure 93-4 A massive pleural effusion associated with a pancreatic pseudocyst. **A**, Chest radiograph demonstrates a massive pleural effusion in the right hemithorax. **B**, CT scan of the upper abdomen performed after pleural drainage shows the cephalad extension of the pseudocyst (*asterisk*) through the right crural insertion (*arrowhead*) and the esophageal hiatus. (Courtesy Dr. S. Navarro, Hospital Clinic, Universitat de Barcelona, Barcelona.)

usually reveal the presence of a pseudocyst and occasionally may even show the pancreaticopleural fistula¹²⁸ (see Fig. 93-4). Endoscopic retrograde cholangiopancreatography provides additional information on ductal structures and may demonstrate passage of contrast material from the pancreatic duct or a pseudocyst into the peritoneal cavity, although visualization of the fistula may be difficult.^{127,129} Endoscopic retrograde cholangiopancreatography and computed tomographic scanning together provide complementary information, which is especially useful if the patient has to undergo surgical intervention.

Patients with chronic pancreatic disease–related pleural effusions should be treated initially with nasogastric tube suction, no oral intake, parenteral nutrition, and therapeutic thoracenteses as needed to improve symptoms. Inhibition of pancreatic secretion with octreotide has been shown to be useful in promoting the closure of pancreaticopleural fistulas in some cases.¹³⁰ Nonetheless, if after 2 to 3 weeks of medical therapy the pleural fluid continues to accumulate and the patient remains symptomatic, surgery to close the fistula should be considered.

OTHER MANIFESTATIONS

A condition called *autoimmune* or *sclerosing pancreatitis* has been linked to the presence of elevated serum IgG₄ concentrations.¹³¹ IgG₄-related disease is a fibroinflammatory condition characterized by a dense lymphoplasmacytic infiltrate rich in IgG₄-positive plasma cells, a swirling appearance of fibroblasts called a “storiform” fibrosis, and, sometimes, elevated serum IgG₄ concentrations.¹³² Furthermore, IgG₄-related disease has been recognized as a systemic condition involving virtually every organ, including the lung; all components of the respiratory system may be implicated, such as parenchymal inflammatory pseudotumor, interstitial pneumonia, central airway stenosis, and mediastinal fibrosis; lung involvement usually improves along with improvement of pancreatitis when treated with glucocorticosteroids.¹³³⁻¹³⁵

KIDNEY DISEASES

Acute and chronic renal diseases are associated with a variety of respiratory manifestations. Pulmonary edema can develop with either acute or chronic renal disease, and pleural disease, pulmonary calcification, and sleep apnea syndrome are fairly common with chronic renal disease. Historically, treatment with hemodialysis caused transient changes in pulmonary gas exchange. These disorders are discussed in this section. Systemic necrotizing vasculitis and diseases associated with autoantibodies, which usually affect both the lung and the kidney, are considered in Chapters 60 and 67.

PULMONARY EDEMA

Pulmonary edema is common in patients with acute or chronic renal functional impairment. A variety of conditions may favor edema formation: fluid overload, left ventricular failure, hypoalbuminemia, and increased pulmonary microvascular permeability. The relative importance of increased microvascular permeability on the one hand versus left ventricular failure on the other has caused controversy for decades. Autopsy findings showing the presence of protein-rich edema fluid, hyaline membranes, and alveolar hemorrhage^{136,137} all pointed to increased pulmonary vascular permeability as the likely mechanism of pulmonary edema formation, as discussed in Chapter 62. The demonstration of an increased protein content in edema fluid sampled directly by endotracheal aspiration reinforced this hypothesis.¹³⁸ Furthermore, pulmonary edema has been reported in the absence of volume overload and in the presence of normal intracardiac and pulmonary wedge pressures.

In contrast, studies using a double-isotope technique have failed to show a significant accumulation of radiolabeled transferrin in patients with renal injury and pulmonary edema.¹³⁹ The rate of protein accumulation in patients with impaired renal function was similar to that in

patients with cardiogenic pulmonary edema and in normal volunteers, and was significantly lower than in patients with ARDS; these observations suggest that pulmonary edema in some if not most patients with renal disease is probably not related to increased pulmonary vascular permeability.¹³⁹

Heart failure is believed to play an important role in the development of pulmonary edema associated with chronic renal disease. Cardiac disorders are common in end-stage renal dysfunction, and a variety of factors, including hypertension, diabetes mellitus, anemia, surgical arteriovenous fistulas, and ischemic heart disease, may adversely affect cardiac function.^{140,141} Left ventricular dysfunction may be reversible after dialysis or renal transplantation, which suggests that patients with chronic renal impairment may have a specific “uremic cardiomyopathy.”^{140,142,143}

Subclinical lung congestion in patients with chronic renal insufficiency may reduce lung volumes and maximal expiratory flow rates, which usually reverse after hemodialysis.¹⁴⁴⁻¹⁴⁶ In contrast to the findings in patients with left ventricular dysfunction,¹⁴⁷ subclinical pulmonary edema in renal injury is not associated with bronchial hyperresponsiveness, either before or after hemodialysis.¹⁴⁸

From a clinical standpoint, most instances of pulmonary edema associated with renal impairment, both acute and chronic, involve increased intravascular volume from abnormal left ventricular function and fluid overload. Accordingly, its treatment should essentially consist of removal of excess body fluid with dialysis.

PLEURAL DISEASE

Approximately 20% to 40% of patients who die of chronic renal insufficiency have fibrinous pleuritis detected at autopsy.^{136,149} This fibrinous pleuritis can be manifested as pleuritic chest pain with pleural friction rubs,¹⁵⁰ pleural effusion,¹⁵¹ or fibrothorax.^{152,153}

Pleural effusions were detected in 20% of 257 hospitalized patients receiving long-term hemodialysis; the most common symptom was dyspnea.¹⁵⁴ Other patients may be asymptomatic or they may present with fever, chest pain, or cough. The effusions usually are unilateral and, in some cases may be large, occupying more than 50% of the hemithorax. In one study, the pleural fluid was transudative in about two thirds of the patients and exudative in the remainder.¹⁵⁴ In patients with exudates, the leukocyte count revealed a predominance of lymphocytes, and the biopsy specimens usually demonstrated chronic fibrinous pleuritis.¹⁵⁵ The pathogenesis of “chronic uremic pleuritis” associated with renal dysfunction is not known, but it is probably related to the effect of retained metabolic toxins.

The effusion usually disappears gradually after several weeks of dialysis but, in about 25% of patients, it may persist, progress, or recur. If fibrothorax develops and produces a symptomatic restrictive ventilatory impairment, surgical decortication should be considered.^{152,153}

PULMONARY CALCIFICATION

Metastatic calcification is a common complication of chronic renal disease that may affect many visceral organs and is found in 60% to 80% of dialysis patients at autopsy

or by bone scintigraphy.¹⁵⁶ Similar diffuse calcifications may be found in other systemic or pulmonary conditions.¹⁵⁷ Pulmonary involvement is common, but it is generally undetectable by ordinary chest films and most patients are asymptomatic.¹⁵⁸ At times, the chest radiograph or computed tomogram may show nodular opacities less than 2 mm in diameter that can be diffuse or localized (see Fig. 95-2). The opacities are relatively stable, in contrast to what would be seen with infectious processes. Pulmonary function tests may reveal a restrictive ventilatory defect and/or a reduction in DL_{CO} .

The pathogenesis of pulmonary calcification in patients with chronic renal insufficiency is complex; several factors—in concert—may play a role: (1) the effect of chronic acidosis, which leaches calcium from bones; (2) the effect of intermittent alkalosis, which favors the deposition of calcium salts; (3) the effect of hyperparathyroidism, which causes bone reabsorption and intracellular hypercalcemia; and (4) the effect of low glomerular filtration rate, which causes hyperphosphatemia and a greatly elevated calcium-phosphorus product.¹⁵⁶

The diagnosis of pulmonary calcification can be confirmed by pulmonary uptake during technetium-99m-diphosphonate scanning (see Fig. 95-3).¹⁵⁹ Treatment is generally unsatisfactory and consists of maintaining adequate dialysis, lowering the calcium-phosphorus product, and treating hyperparathyroidism, when present; renal transplantation may sometimes improve or actually worsen the condition.¹⁵⁶

SLEEP APNEA

Disturbed sleep, including sleep apnea, has long been recognized in patients with end-stage renal disease. (Other causes of sleep apnea, as well as its pathophysiology and treatment, are described in Chapter 88.) The mounting evidence in favor of a high prevalence of sleep apnea in dialysis patients—greater than 50%¹⁶⁰—has been reinforced by the results of comparisons between patients on standard thrice-weekly hemodialysis and closely matched control subjects from the community-based Sleep Heart Health Study: dialysis patients had a fourfold increase in sleep apnea and episodes of severe nocturnal hypoxemia, after adjusting for comorbid conditions that might have affected outcome.¹⁶¹

Various mechanisms have been proposed to explain the high prevalence of sleep apnea in patients with end-stage renal disease undergoing hemodialysis. Perhaps the most persuasive of the pathogenetic speculations involves the importance of fluid overload and the shift of fluid to the upper body during sleep, thereby facilitating airway obstruction.¹⁶² Support for this postulate comes from the increased pharyngeal resistance that accompanies shifts of fluid produced by applying high pressure to the lower body in healthy subjects.¹⁶³ Follow-up studies using the same methodology documented an increase in upper airway collapsibility.¹⁶⁴ Such studies support the hypothesis that fluid displacement during recumbency predisposes to obstructive sleep apnea.

Accumulation of uremic toxins might also play a role, independently or in conjunction with fluid overload, in the pathogenesis of sleep disorders. Increasing the frequency and length of nocturnal hemodialysis, which does

not distinguish between the presence of toxins and fluid overload as possible mechanisms, caused a significant decrease in the severity of sleep apnea in all 14 patients in whom it was tried,¹⁶⁵ thus offering a potential, but logistically complicated, solution to an otherwise difficult-to-treat and serious clinical problem.

Standard treatment of obstructive sleep apnea might be beneficial, but experience in patients with end-stage kidney disease is limited.¹⁶⁶ There are anecdotal reports of improvement after renal transplantation,¹⁶⁷ but according to one report, only 3 of 18 patients had significant improvement after the procedure.¹⁶⁸

HEMODIALYSIS-INDUCED HYPOXEMIA

Another clinical problem that was associated with end-stage renal disease and hemodialysis—now largely of historic interest only—was the prompt reduction in arterial PO_2 of 10 to 15 mm Hg after initiation of dialysis, which reached a nadir after 30 to 60 minutes and persisted for the duration of the procedure.¹⁶⁹⁻¹⁷¹ The severity of hypoxemia varied according to the type of dialysis membrane and the chemical nature of the dialysate buffer.^{172,173} Once popular explanations for the phenomenon, pulmonary vascular leukostasis and activation of complement, have since been excluded. Exposure of blood to certain dialysis membranes activates the alternative complement pathway and, within minutes, C3a and C5a are generated, which may induce intrapulmonary sequestration of leukocytes and a fall in circulating leukocytes. Based on the temporal association between the onset of hypoxemia and the transient leukopenia, it was postulated that the decrease in arterial PO_2 resulted from ventilation-perfusion mismatching due to leukostasis in small pulmonary vessels.¹⁷⁴ However, studies using the multiple inert gas elimination technique ruled out ventilation-perfusion mismatching as the principal mechanism of hypoxemia,¹⁷⁵⁻¹⁷⁷ even though Romaldini and colleagues¹⁷⁶ showed a tendency for ventilation-perfusion matching to improve during the dialysis procedure, which was most likely explained by a dialysis-induced decrease in extravascular lung water. Furthermore, hypoxemia was observed during dialysis with membranes that do not cause leukopenia.¹⁷⁸

Currently, the most accepted explanation for the decrease in arterial PO_2 during hemodialysis is the onset of hypoventilation associated with the removal of carbon dioxide by the dialysate, which is substantial with acetate buffer but minimal with bicarbonate buffer¹⁷⁹; in addition, acetate buffer may further reduce respiratory carbon dioxide elimination due to carbon dioxide consumption during acetate metabolism.¹⁸⁰ In one study of patients undergoing hemodialysis with acetate buffer, minute ventilation dropped from an average of 7.2 L/min to 5.7 L/min within 15 minutes of the start of hemodialysis.¹⁸¹ The alveolar-arterial PO_2 difference value during hemodialysis remains stable despite a significant fall in arterial PO_2 .^{171,176} An additional consequence of the nonrespiratory carbon dioxide “unloading” was to destabilize resting ventilation, which was manifested by an irregular breathing pattern, with the development of periodicity and sometimes apneas.^{181,182}

Today, the former complications of leukopenia and hypoxemia during hemodialysis have been largely elimi-

nated by the use of synthetic (inert) membranes, which do not activate complement and thus avoid leukopenia, and dialysates such as bicarbonate, which do not remove carbon dioxide. Supplemental oxygen should still be given during the procedure to patients with coexisting cardiopulmonary diseases.

Key Points

- Gastroesophageal reflux, a common disorder, may cause recurrent chest pain, varying from heartburn to myocardial ischemia-like distress, may provoke or exacerbate chronic cough, and may trigger asthma attacks or worsen other underlying respiratory conditions.
- Inflammatory bowel diseases, ulcerative colitis more so than Crohn disease, have been associated with a variety of chronic pulmonary diseases, particularly of the airways; these include asthma, chronic bronchitis, and bronchiectasis, and, less commonly, disorders of the lung parenchyma, such as interstitial fibrosis and cryptogenic organizing pneumonia.
- Patients with end-stage liver disease can have characteristic pulmonary complications: hepatic hydrothorax develops in 5% to 10%; hepatopulmonary syndrome, characterized by hypoxemia from marked dilation of pulmonary capillaries, develops in as many as 20%; portopulmonary hypertension (mean PPA > 25 mm Hg) develops in another 6% of patients.
- Episodes of severe acute pancreatitis are associated with a high frequency of pulmonary complications, especially hypoxemia, pleural effusions, and acute respiratory distress syndrome, which are major causes of excess morbidity and mortality.
- Diseases of the kidney are important causes of pulmonary edema, pleural disease, pulmonary calcifications, and sleep apnea, some of which may be alleviated by dialysis and/or renal transplantation.

THROMBOSIS AND DISORDERS OF COAGULATION

Inherited Thrombophilia

Coagulopathies and Platelet Disorders

COMPLICATIONS OF TRANSFUSION

Transfusion-Associated Acute Lung Injury

INTRODUCTION

Hematologic diseases and their specific therapies can adversely affect several aspects of cardiopulmonary function, by reducing the oxygen-carrying capacity of the blood, by impairing pulmonary vascular function and pulmonary immune defenses, and by direct pulmonary parenchymal damage. This chapter reviews the clinical manifestations, epidemiology, pathophysiology, and treatment of pulmonary complications of disorders of the hematologic system.

RED BLOOD CELL DISORDERS

ANEMIA

Anemia is defined as a reduction in the number of circulating red blood cells. By decreasing oxygen-carrying capacity of the blood, anemia can impair cardiopulmonary function. However, because multiple compensatory mechanisms exist to adjust to a reduced oxygen-carrying capacity of blood, the signs and symptoms induced by anemia depend on the degree of anemia, the rate at which it evolves, the oxygen demands of the patient, and the presence of chronic cardiopulmonary disease. For instance, in resting adults subjected to acute isovolemic anemia, oxygen delivery can be maintained at hemoglobin concentrations as low as 5 g/dL,¹ a finding also seen in individuals with chronic severe anemia.² As such, anemia, even when severe, rarely causes heart failure or pulmonary edema and, when it does, it is likely that heart failure from chronically high cardiac output is superimposed on some other coexisting cardiac abnormality. From the hemodynamic standpoint, as the hemoglobin level decreases (particularly with hemoglobin values < 7 g/dL), cardiac output increases, filling pressures tend to decrease, and systemic and pulmonary vascular resistances decrease. Further, these changes are readily reversible after red blood cell transfusions.^{2,3} Finally, when anemia is severe, in the absence of coexisting cardiopulmonary disease, gas exchange is usually well maintained.

Pulmonary hypertension (PH) is an increasingly recognized complication of chronic hereditary and acquired hemolytic anemias. Remarkably, virtually every cause of hemolytic anemia has been associated with PH (Table

94-1). The PH associated with hemolytic disorders is now considered in the Group 5 classification of pulmonary hypertension, characterized by unclear/multifactorial mechanisms (see Chapter 58).^{3a} In contrast, there have been no reports of PH associated with nonhemolytic anemias such as the anemia of chronic disease or iron deficiency anemia. This suggests that the hemolytic component of anemia is necessary for the development of PH, which is discussed in detail in the section on [hemoglobinopathies](#).

POLYCYTHEMIA

Polycythemia is characterized by an abnormally high hematocrit (>48% and >52% in women and men, respectively), hemoglobin concentration (>16.5 or >18.5 g/dL in women and men, respectively), or red blood cell count. These measurements are dependent on the plasma volume as well as the red blood cell mass; thus, before classifying a patient as having true polycythemia, one must exclude a decrease in plasma volume as the etiology for these abnormalities. A state of chronically reduced plasma volume with elevated hemoglobin or hematocrit has been called Gaisböck disease,⁴ spurious polycythemia, stress erythrocytosis, apparent polycythemia, and pseudopolycythemia and has been associated with use of diuretics, alcohol, obesity, hypertension, and renal disease. On the other hand, patients with true elevations in red blood cell mass have absolute polycythemia and are categorized in primary and secondary forms. Primary polycythemia is caused by an acquired or inherited mutation such as in the *JAK2* gene,⁵ leading to an abnormality within red blood cell progenitor cells; it includes polycythemia vera and rare familial variants (e.g., activating mutations of the erythropoietin receptor or Chuvash polycythemia). Secondary polycythemia is caused by a circulating factor stimulating erythropoiesis, usually related to the production of erythropoietin as a physiologic response to chronic hypoxia (e.g., chronic hypoxic lung disorders and disorders affecting hemoglobin oxygen affinity), but can also result from erythropoietin-secreting tumors.

Most of the symptoms of polycythemia are related to an increase in blood viscosity, which leads to impairment in systemic and pulmonary blood flow. Thromboembolic events have been described in approximately 30% of patients with polycythemia vera and account for 31% of their

Table 94-1 Hemolytic Disorders Associated with Pulmonary Hypertension

Hemoglobinopathies
Sickle cell disease
Thalassemia intermedia and major
Hb Mainz unstable hemoglobin hemolytic anemia
Red cell membranopathies
Hereditary spherocytosis
Hereditary stomatocytosis
Paroxysmal nocturnal hemoglobinuria
Alloimmune hemolytic anemia

deaths.⁶ Pulmonary nodular lesions secondary to thrombosis, stasis, or infarction have been described in these patients.⁷ Late-stage polycythemia vera, which is characterized by myelofibrosis, may cause pulmonary and pleural masses that are related to extramedullary hematopoiesis.⁸

PH has been reported in patients with polycythemia and other myeloproliferative disorders (recently reviewed by Machado and Farber).^{7,9-11,11a} In a retrospective review, 26 patients—12 with myeloid metaplasia, 5 with essential thrombocythemia, 6 with polycythemia vera, 2 with myelodysplastic syndrome, and 1 with chronic myeloid leukemia—had echocardiographic or hemodynamic evidence of PH. Interestingly, the median survival after the diagnosis of PH was 18 months and the majority of deaths were related to cardiopulmonary causes, suggesting that the presence of PH was a direct cause of death.⁹ In a subsequent retrospective study of 10 patients with PH and myeloproliferative disorders (8 with polycythemia vera and 2 with essential thrombocytosis), 6 patients had chronic, thromboembolic PH and 4 had unexplained PH; these findings were most likely associated with the myeloproliferative disorder because other risk factors for PH could not be identified.¹² In a cohort of 14 patients with Chuvash polycythemia, the prevalence of PH (defined as an estimated pulmonary artery systolic pressure ≥ 35 mm Hg) was 36%.¹¹ The pathogenesis of PH in these disorders is not well established but can involve chronic thromboembolic disease or hypercoagulability and hyperviscosity leading to in situ thrombosis, as well as hemoglobin-dependent scavenging of endothelium-derived *nitric oxide* (NO)¹³⁻¹⁷ and up-regulation of HIF-1 α -mediated pathways, such as endothelin-1.¹¹

In patients with polycythemia vera, the mainstay of therapy is phlebotomy and myelosuppression with hydroxyurea, to keep the hematocrit below 42% in women and 45% in men, and antithrombotic therapy with aspirin or anagrelide.^{18,19} In case series, treatment of the myeloproliferative disorder has been shown to improve PH.⁹ In patients with chronic hypoxic disorders such as *chronic obstructive pulmonary disease* (COPD) and interstitial lung disease, long-term oxygen therapy should reduce the number of patients

who become severely polycythemic. In patients with COPD and severe polycythemia, phlebotomy—to achieve a hematocrit of about 50%—is associated with both a decrease in mean pulmonary artery pressure and in pulmonary vascular resistance, as well as an improvement in exercise performance.²⁰ However, the use of phlebotomy should be reserved as adjunctive therapy in the management of markedly polycythemic and symptomatic patients who remain significantly polycythemic despite appropriate long-term oxygen therapy.

HEMOGLOBINOPATHIES

SICKLE CELL DISEASE

Sickle cell anemia, the most common and most severe form of sickle cell disease, is seen in individuals who are homozygous for a single nucleotide substitution in the β globin gene. This results in the synthesis of *hemoglobin S* (Hb S), a structural variant that, when deoxygenated, is much less soluble than normal hemoglobin (Hb A).^{21,22} Deoxygenated Hb S polymerizes and aggregates inside sickled erythrocytes as they traverse the microcirculation. Rigid, dense, and sickled cells can become entrapped in the microcirculation, a process that is enhanced by their increased propensity to adhere to endothelium. Mechanistic studies in transgenic mice expressing exclusively human Hb S suggest that microvascular occlusion results in ischemia and reperfusion injury, which promotes inflammatory, thrombotic, and oxidant stress.²³⁻²⁶ In patients with sickle cell disease, vaso-occlusion leads to the frequent episodes of bone pain and acute chest syndrome that complicate sickle cell disease. Furthermore, the membrane of erythrocytes containing intracellular Hb S polymer is constantly exposed to mechanical and oxidant injury as the erythrocytes traverse the microcirculation. Ultimately, cumulative membrane damage shortens red cell life span so that sickle cell disease is characterized by a chronic hemolytic anemia. Intravascular hemolysis releases cell-free hemoglobin into the plasma, which scavenges NO and releases red blood cell arginase into the plasma, which catabolizes arginine, the substrate for NO synthesis.^{14,27,28} Intravascular hemolysis thus produces a state of endothelial dysfunction, vascular proliferation, and pro-oxidant and proinflammatory stress.²⁹⁻³⁵

It is estimated that around 250,000 children worldwide are born with homozygous sickle cell anemia every year.³⁶ Approximately 0.15% of African-Americans are homozygous for sickle cell disease, and 8% have the sickle cell trait. Despite significant improvements in the life expectancy of patients with sickle cell disease, estimates of the median age at death range from 48 to 58.5 years for women and 42 to 53 years for men.^{37,38}

Acute and chronic pulmonary complications of sickle cell disease are common but often underappreciated by health care providers. Acute complications include asthma and the *acute chest syndrome* (ACS), while chronic complications include pulmonary fibrosis, PH, and cor pulmonale. Pulmonary complications account for a large proportion of deaths among adults with sickle cell disease.^{37,39,40} According to the *Cooperative Study of Sickle Cell Disease* (CSSCD), a prospective multicenter study of 3764 patients, more

than 20% of adults presumably had fatal pulmonary complications of sickle cell disease.³⁷ Among the 299 patients enrolled in the long-term follow-up study of patients who participated in the *Multicenter Study of Hydroxyurea in Sickle Cell Anemia* (MSH), pulmonary disease was the most common cause of mortality, accounting for 28% of all deaths.⁴¹

Acute Chest Syndrome

ACS represents a lung injury syndrome in patients with sickle cell disease that is related to the increased membrane permeability that characterizes the *acute respiratory distress syndrome* (ARDS). In a patient with sickle cell disease, ACS is clinically defined by the development of a new pulmonary opacity involving at least one complete lung segment, consistent with alveolar consolidation, not atelectasis, and accompanied by chest pain, fever, tachypnea, wheezing, or cough.⁴²

Epidemiology. ACS is the second most common cause of hospitalization in patients with sickle cell disease and the leading cause of both admission to an intensive care unit and premature death.^{37,40} More recently, however, increased awareness, the chronic use of hydroxyurea, and the early and aggressive use of transfusion therapy appear to have decreased ACS-related morbidity and mortality, as evidenced by a lower rate of ACS in a recently completed multicenter trial of inhaled NO for vaso-occlusive crises.⁴³

ACS can develop in any of the sickle hemoglobinopathies but is more common in individuals with homozygous sickle cell disease (Hb SS). In the CSSCD, there was a 29% incidence of the ACS in 3751 subjects over a 2-year period, representing an attack rate of 12.8 episodes per 100 patient-years for Hb SS disease.³⁷ The incidence was higher in children than in adults (24.5 events vs. 8.8 events per 100 patient-years). Up to half of ACS episodes develop in association with vaso-occlusive pain crisis, and a sizable proportion of patients will have a painful event within 2 weeks of the diagnosis.^{44,45} Because up to 20% of patients admitted with acute vaso-occlusive pain crisis will develop ACS in the first 3 days of hospitalization, physicians must be vigilant for this common and potentially lethal complication.

Steady-state laboratory parameters associated with an increased risk for the development of ACS include an elevated white blood cell count, a higher steady-state hemoglobin level, and a lower steady-state fetal hemoglobin level.^{44,45} In children, a number of studies now suggest that asthma is a risk factor for the development of ACS.⁴⁶⁻⁴⁸ Other clinical events that appear to increase the risk of (or are associated with) the development of ACS include major surgical procedures, acute rib infarcts, avascular necrosis of the hips, pregnancy, use of narcotics, acute anemic events, and previous pulmonary events.^{44,45}

During acute hospitalization for vaso-occlusive crisis, the development of ACS is often preceded by an abrupt drop in hemoglobin levels (mean decrease of 0.78 g/dL from steady-state values) and increases in markers of hemolysis, such as *lactate dehydrogenase* (LDH). ACS may also be preceded by a drop in the platelet count, and levels less than 200,000 per μ L constitute an independent risk factor for ACS severity, associated with increased risk of neurologic complica-

tions and mechanical ventilation. In our units, we monitor trends in hemoglobin and platelet counts and pay careful attention to patients with drops in steady-state values.

Pathophysiology. Three major mechanisms appear to be involved in the pathogenesis of ACS: infection, bone marrow fat embolization, and direct red cell intravascular sequestration causing lung injury and infarction (Table 94-2, Fig. 94-1).

The most common etiology of ACS in both children and adults is infection by a community-acquired pathogen (eFig. 94-1), followed by an excessive inflammatory lung injury response. More than 80% of adults with sickle cell disease report a history of having been admitted to the hospital for "pneumonia."²⁹ The National Acute Chest Syndrome Study Group analyzed 670 episodes of ACS in 538 patients with sickle cell disease to determine the cause, outcome, and response to therapy, and respiratory samples obtained from sputum and bronchoalveolar lavage were analyzed for viral and bacterial infections.⁴² Among the infectious agents identified most frequently were atypical bacteria and viruses, including *Chlamydia pneumoniae*

Table 94-2 Causes of 670 Episodes of Acute Chest Syndrome*

Cause	Episodes (n) and (%) of total	NO. OF EPISODES OF ACUTE CHEST SYNDROME IN EACH AGE GROUP		
		0-9 yr (n = 329)	10-19 yr (n = 188)	≥20 yr (n = 153)
Fat embolism, with or without infection [†]	59 (8.8)	24	16	19
<i>Chlamydia</i> [‡]	48 (7.2)	19	15	14

Bacteria	30 (4.5)	13	15	12
Mixed infections	25 (3.7)	16	6	3
<i>Legionella</i>	4 (0.6)	3	0	1
Miscellaneous infections	3 (0.4)	0	3	0
Infarction [¶]	108 (16.1)	50	43	15
Unknown [#]	306 (45.7)	139	88	79

*Data on one episode were excluded because the patient's birth date was not known.

[†]Nineteen of the episodes of pulmonary fat embolism were associated with infectious pathogens.

[‡]This category included episodes in which *Chlamydia* alone was identified but not episodes involving mixed infections or pulmonary fat embolism.

[§]This category included only episodes in which *Mycoplasma pneumoniae* or *Mycoplasma hominis* was identified, but not episodes involving mixed infections, *Mycobacterium tuberculosis*, or pulmonary fat embolism.

^{||}This category included two cases of tuberculosis and one case of *Mycobacterium avium* complex infection.

[¶]A pulmonary infarction was presumed when the results of the analysis for pulmonary fat embolism, bacterial studies, viral isolation studies, and serologic tests were complete and were all negative.

[#]The cause of episodes for which some or all of the diagnostic data were incomplete and no etiologic agent was identified was considered to be unknown.

VICIOUS CYCLE OF VASO-OCCLUSIVE CRISIS AND ACUTE CHEST SYNDROME

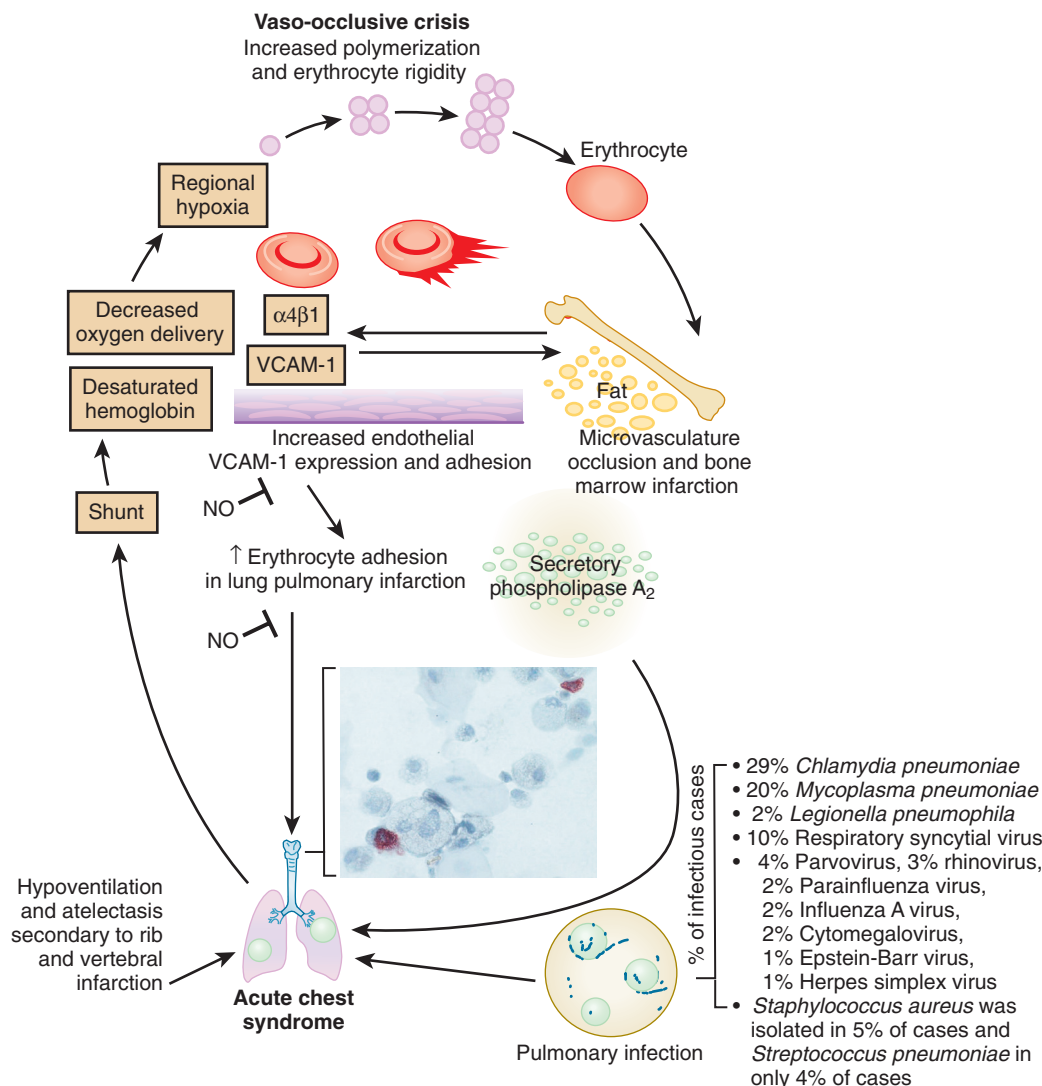

Figure 94-1 Pathogenesis of the acute chest syndrome. Three major triggers are associated with the development of acute chest syndrome (ACS): infection, bone marrow fat embolization, and direct red cell intravascular sequestration causing lung injury and infarction. Lung injury results in ventilation-perfusion mismatch/shunt and hypoxemia, which leads to increased hemoglobin S polymerization, and erythrocyte vaso-occlusion. This worsens bone marrow infarction and pulmonary vaso-occlusion to promote a vicious cycle. Fat embolization can be diagnosed by Oil Red O staining of pulmonary alveolar macrophages, revealing the characteristic red lipid inclusions, as shown in the panel. Common infectious organisms and other causes of ACS are listed in Table 94-2. NO, nitric oxide.

(29%), *Mycoplasma pneumoniae* (20%), *Legionella pneumophila* (2%), respiratory syncytial virus (10%), parvovirus (4%), rhinovirus (3%), parainfluenza virus (2%), influenza A virus (2%), cytomegalovirus (2%), Epstein-Barr virus (1%), and herpes simplex virus (1%). Community-acquired encapsulated bacteria were rarely isolated, despite the fact that patients with Hb SS disease rarely have normal splenic function. *Staphylococcus aureus* was isolated in 5% of cases and *Streptococcus pneumoniae* in only 4% of cases. Cases of severe ACS related to outbreaks of seasonal influenza have also been described.^{49,50}

Fat embolization syndrome is the second most common cause of the ACS. It arises as a complication of vaso-occlusive pain crisis involving multiple bones, which results in bone marrow edema, infarction, and necrosis. As a consequence, bone marrow contents are released into the systemic circulation and trapped in the pulmonary circulation,

producing acute PH, severe lung inflammation, and hypoxemia (Fig. 94-2) (eFig. 94-2).⁵¹ Bone marrow fat released into the bloodstream is also converted by secretory phospholipase A₂ to free fatty acids, which can produce direct inflammatory lung injury.⁵²

Finally, in approximately 20% of patients, direct lung infarction or vaso-occlusion is associated with the development of ACS, with a small percentage of patients actually developing triangular-shaped pulmonary infarction (eFig. 94-3), sometimes followed by central cavitation.⁵³ Direct pulmonary arterial in situ thrombosis is also seen in patients with ACS. A French study evaluated the presence of pulmonary artery thrombosis by computed tomography (CT)–pulmonary angiography in 125 consecutive patients with 144 episodes of ACS and noted a 17% prevalence of subsegmental thromboembolism without evidence of peripheral venous thrombosis in any of their cases.⁵⁴

Figure 94-2 Fat embolization in acute chest syndrome. **A**, Chest CT scan of a patient with acute chest syndrome and fat embolization syndrome. **B**, Postmortem examination specimen of a patient who died suddenly during an episode of vaso-occlusive crisis and acute chest syndrome demonstrating bone marrow elements (arrows) lodged in the small pulmonary artery.

A potential role for hemolysis-derived plasma-free hemoglobin and free heme as novel mechanisms in ACS is emerging. Ghosh and colleagues⁵⁵ administered lysed red blood cells into the circulation of sickle cell mice, which resulted in increased pulmonary vascular permeability without affecting permeability in other organs; moreover, preliminary studies from the same group have demonstrated that intravenous administration of heme to sickle cell mice induces severe and lethal acute lung injury. These data suggest that plasma-free hemoglobin and/or heme specifically may contribute directly to lung injury. The relationship between increased intravascular hemolysis and thrombocytopenia indicates that a possible *thrombotic thrombocytopenic purpura* (TTP)-like mechanism may exist in a subset of patients with ACS as suggested by studies demonstrating that free hemoglobin may inhibit activity of ADAMTS13, a protease whose deficiency underlies most cases of TTP.⁵⁶⁻⁵⁸

Clinical Features and Evaluation. The clinical features at presentation are age dependent, which likely reflects the different etiologies of ACS in different age groups, with children having a higher proportion of infectious etiologies in comparison with adults, who tend to have fat embolization as a major etiology. Overall, 80% of patients present with fever, 62% with cough, and approximately 40% have chest pain, tachypnea, dyspnea, and abdominal, arm, leg, rib, or sternal pain.⁴² Most adult patients present with severe extremity or chest pain and 24 to 72 hours later develop ACS. Reactive airway disease is observed in 13% of cases of ACS and is much more common in children.

ACS is associated with signs of systemic inflammation, with mean peak temperatures of 38.9° C and mean white blood cell counts of 23,000 cells/ μ L.⁴² As mentioned earlier, although a high steady-state hemoglobin level is a major risk factor for developing ACS, the acute presentation is often associated with a drop in hemoglobin levels (mean decrease of 0.78 g/dL from steady-state levels) and increases in markers of hemolysis. A platelet count less than 200,000 per μ L appears to be a marker of ACS severity, associated with increased risk of neurologic complications and mechanical ventilation.⁴³ Secretory phospholipase A₂ levels are elevated early in the course of ACS, even before the

development of radiographic changes, and have been used to predict the onset of the syndrome.⁵⁹

Because the clinical manifestations can be indistinguishable from the other causes of ACS, the diagnosis of pulmonary fat embolization syndrome relies on the identification of Oil Red O-positive lipid accumulations within alveolar macrophages (see Fig. 94-1). In a 30-center clinical trial, the National Acute Chest Syndrome Study Group identified fat embolization syndrome in 16% of ACS cases in adults and children on the basis of positive lipid accumulations in alveolar macrophages.⁴² Traditionally bronchoscopy has been used as the diagnostic modality of choice for the diagnosis of pulmonary fat embolization syndrome. However, induced sputum may be a noninvasive alternative; in one study, induced sputum sampling of alveolar macrophages was found to have a similar yield as samples obtained from bronchoalveolar lavage, with a modest but significant correlation between the two measurements ($r = 0.65$).⁶⁰

Some patients with ACS manifest evidence of *systemic fat embolization*, also called the *acute multiorgan failure syndrome*. This syndrome should be suspected in patients presenting with acute multiorgan failure characterized by the development of acute hypoxic respiratory failure, right heart failure, renal and hepatic dysfunction, alterations in mental status, seizures, thrombocytopenia, and coagulopathy.^{61,62} In patients with ACS, those with lipid-laden macrophages in induced sputum have significantly more extrathoracic pain, evidence of fat emboli, more neurologic symptoms, a lower platelet count, and higher transaminase levels than do those without lipid-laden macrophages.⁶⁰ This suggests that the fat embolization syndrome is both a major cause of ACS and has a more severe course with systemic complications.

The mean length of hospitalization for ACS is 10.5 days, compared with 3 to 4 days for uncomplicated vaso-occlusive pain crisis. Thirteen percent of all patients with ACS require mechanical ventilation, and the overall mortality is 3% for all patients and 9% for adults. Risk factors for mechanical ventilation and poor outcome include a platelet count less than 200,000 per μ L (likely indicative of the fat embolization syndrome), a larger number of lobes involved on chest radiograph, and a self-reported or medical record history of cardiac disease. The latter complication is now

thought to represent occult PH and cor pulmonale. In fact, in a study of 84 consecutive hospitalized patients with ACS, 13% of patients manifested right heart failure, a subgroup that had the highest risk for mechanical ventilation and death.⁶³ Thus, PH and right heart dysfunction likely represent a major comorbidity during ACS, and right heart failure should be considered in patients presenting with shock or severe hypoxemia. Interestingly, despite these issues, the outcome of patients with severe ACS on mechanical ventilation is better than that of patients with ARDS, with a mortality rate of 19% in contrast to the approximate 30% mortality rate reported in current ARDS studies.⁴²

Treatment. In the outpatient setting, patients with a history of ACS should be treated with hydroxyurea because hydroxyurea has been shown to reduce the risk of developing ACS by approximately 50%.^{64,65} A chronic transfusion regimen is also effective in reducing the incidence of ACS.⁶⁶ Because the triggers and risk factors for ACS are well known, clinical surveillance plus aggressive and early therapy of this patient population are likely to improve prognosis. This could be accomplished by close monitoring of patients during a vaso-occlusive crisis, during a febrile illness, and in the postoperative state.

If ACS develops, a range of treatment strategies is recommended, as outlined in Table 94-3. Oxygen therapy should be given routinely to maintain oxygen saturation above 92%. Aggressive pain management and incentive spirometry can minimize chest wall splinting, with consequent relief of atelectasis and alveolar hypoxia. In fact, the use of incentive spirometry has been shown to decrease the incidence of new pulmonary opacities in patients admitted with vaso-occlusive pain affecting the chest wall.⁵³

Given the high prevalence of infectious etiologies for ACS, we recommend the use of empirical antimicrobial therapy in all patients. Considering the high prevalence of

atypical bacteria and encapsulated organisms, empirical coverage should include agents, such as the macrolides or fluoroquinolones, effective against these organisms. It is also important to consider alternative organisms such as methicillin-resistant *S. aureus* or influenza viruses, especially in patients not responding to therapy or during the annual influenza season.

Blood transfusion remains the mainstay of ACS therapy, although its value has not yet been demonstrated in randomized trials. Acute red cell transfusion increases arterial PO_2 and hemoglobin oxygen saturation and may rapidly resolve the pulmonary event.^{42,67} Transfusion can also increase blood viscosity and the consequent risk of vaso-occlusion, so it is recommended that the hemoglobin level not rise above 11 g/dL. The National Acute Chest Syndrome Study Group found no significant differences in outcomes between patients treated with simple transfusion or with erythrocytapheresis, a red cell exchange, suggesting that simple transfusion is preferred as initial therapy.⁴² For patients with high initial hemoglobin concentrations (>9 g/dL) or with more severe disease, however, erythrocytapheresis is recommended. However, because most patients have a significant decrease in hemoglobin at presentation, the transfusion of 2 to 4 units of packed red cells over 24 to 48 hours can usually be performed without complication. In order to decrease the risk of delayed hemolytic transfusion reactions related to alloimmunization against minor red blood cell antigens, all transfused blood should be matched to Rh, C, E, and Kell antigens.

Some potentially promising treatments have not proven to have a role in ACS. Although treatment with corticosteroids has been shown to reduce the severity of pain and length of hospitalization, this therapy is complicated by a high rate of rebound pain and hospitalization.^{68,69} A study evaluating a slow tapering protocol to maintain the beneficial effects of corticosteroids while limiting rebound pain and re-admission was terminated early because of slow accrual.⁷⁰ The placebo-controlled study by Gladwin and coworkers⁴³ evaluated the role of inhaled NO therapy for patients presenting in vaso-occlusive crisis and did not demonstrate an effect of inhaled NO compared with placebo on the duration of pain crisis, narcotic use, pain scores, or the development of ACS. In a prospective, randomized, open, single-center study of 67 adult patients with ACS, *noninvasive mechanical ventilation* (NIV) use improved respiratory rate and gas exchange but did not reduce the number of patients remaining hypoxemic at day 3 and was associated with greater patient discomfort. Additionally, NIV did not change transfusion rates, pain scores, narcotic dose, or hospital length of stay but instead prolonged length of stay in the step-down unit.⁷¹

Pulmonary Hypertension

PH has emerged as a major threat to the well-being and longevity of patients with sickle cell disease. PH is defined hemodynamically by a *mean pulmonary artery pressure* (PAP) greater than or equal to 25 mm Hg. Sickle cell disease could represent one of the most common causes of PH. Because there are 30 million individuals worldwide with sickle cell disease,⁷⁴ of whom 10% to 30% may have PH, there may be as many as 3 to 9 million patients with the complication.

Table 94-3 Treatment of the Acute Chest Syndrome (ACS)

Oxygen therapy to maintain arterial hemoglobin oxygen saturation above 92%
Pain control and incentive spirometry to reduce chest wall splinting and pulmonary atelectasis
Close clinical observation Monitor PO_2/FIO_2 ratio: Particular attention to diagnosis of worsening respiratory function
Asthma therapy if indicated
Empirical antibiotics Cover typical and atypical respiratory pathogens. Consider the regional and seasonal risk of methicillin-resistant <i>Staphylococcus aureus</i> . Anticipate influenza A or B infections and treat/prevent accordingly.
Transfusion therapy Main indication for transfusion therapy in ACS is worsening respiratory function. Simple transfusion is as effective as erythrocytapheresis in the usual patient. Patients with high initial hemoglobin concentrations (≥ 9 g/dL) or patients with more severe disease should receive erythrocytapheresis. Transfused blood should be matched to Rh, C, E, and Kell antigens, and transfusion records documenting history of prior alloantibodies should be obtained.

Figure 94-3 Pulmonary arteriopathy in sickle cell-related pulmonary hypertension. **A**, Low-power photomicrograph demonstrating pulmonary arterial smooth muscle hypertrophy (hematoxylin and eosin stain). **B**, Higher-power photomicrograph of one of the arteries showing a plexogenic lesion, with medial thickening, laminar intimal hyperplasia, recanalization, and fibrosis (hematoxylin and eosin stain).

Epidemiology. A variety of studies, both retrospective and prospective, have identified a high prevalence of PH in patients with sickle cell disease. Retrospective studies have reported that 20% to 30% of patients with sickle cell disease have an elevated pulmonary artery systolic pressure estimated noninvasively by Doppler echocardiography by a *tricuspid regurgitant jet velocity* (TRV) that is 2 standard deviations above the normal mean value (≥ 2.5 m/sec).^{62,75} Autopsy studies suggest that up to 75% of sickle cell patients have histologic evidence of PH at the time of death (Fig. 94-3).⁷⁷

These data are now corroborated by three prospective studies.^{29,78,79} In the *National Institutes of Health* (NIH) PH echocardiographic screening study, 23% of patients with sickle cell disease had borderline to mild elevations in pulmonary artery systolic pressures (defined by a TRV of > 2.5 to 2.9 m/sec, which corresponds to a pulmonary artery systolic pressure of 30 to 39 mm Hg) and 9% had moderately to severely elevated pressures (defined by a TRV > 3.0 m/sec, which corresponds to a pulmonary artery systolic pressure of approximately 40 to 45 mm Hg).²⁹ Similar rates were found in echocardiographic screening studies performed at two other centers.^{78,79}

Measurement of *N-terminal pro-brain natriuretic peptide* (NT-proBNP), a prohormone released by the right and left ventricular myocardium under pressure stress, in stored plasma samples has shown a high prevalence of abnormal values that may correlate with PH. Of those enrolled in the MSH in 1996, 30% of individuals had elevated levels suggesting the possible presence of PH.⁸⁰ Similarly, among patients enrolled in the CSSCD from 1978 to 1988, 27.6% of adults had elevated levels of NT-proBNP.⁸¹ In both studies, elevated NT-proBNP was independently associated with a higher risk of death.

PH has been shown to increase over time and with increasing age. Two centers independently reported the follow-up of adult sickle patients who on initial echocardiographic screening had normal TRVs. After 2 to 3 years of follow-up, 13% to 15% of these patients developed high TRVs, suggesting an increasing incidence of PH of about 4% to 7% per year.^{72,82} Increasing age is associated with an increased risk of elevated TRV. For example, in the NIH PH

echocardiographic screening study, patients with an elevated TRV were significantly older than patients without (38 ± 19 years for patients with TRV > 3.0 m/sec and 39 ± 12 years for patients with TRV 2.5 to 2.9 m/sec, compared with 34 ± 10 years for patients with TRV < 2.5 m/sec; $P = 0.02$).²⁹ An increasing number of studies suggests that PH is developing in children with sickle cell disease; however, few children have TRV values greater than 3.0 m/sec, and the implications in terms of functional capacity and associated mortality have not been determined.⁸³⁻⁸⁵

Epidemiologic risk factors associated with PH include a history of renal or cardiovascular complications, increased systemic systolic blood pressure, elevations in the marker of hemolysis (LDH), elevated alkaline phosphatase, and low transferrin levels.^{29,80,87} In men, a history of priapism was also an independent factor associated with PH.²⁹ These risk factors have also been observed in recently published studies using right heart catheterization to define PH.⁸⁸⁻⁹⁰ Interestingly, the development of PH was not associated with the number of vaso-occlusive episodes, markers of inflammation, fetal hemoglobin levels, or platelet counts.^{29,80,88-90} Although a high pulmonary artery pressure could also result from the high cardiac output state associated with chronic anemia, this hyperdynamic state does not seem to be a major contributor to significant elevations in pulmonary artery pressures because there has been no report of PH associated with nonhemolytic anemia. In sum, PH represents a component of the systemic vasculopathy of sickle cell disease (characterized by systemic hypertension, renal failure, and priapism).

Finally, three studies have provided new insights into the prevalence of PH in sickle cell disease using the gold standard diagnostic test for the disease, right heart catheterization. In the NIH screening study (2001–2010, median follow-up of 4.4 years),⁹⁰ 86 of the 533 subjects underwent right heart catheterization and, of these, 56 (10.5%) were diagnosed with PH. Similarly, in a screening study of 80 patients from Brazil, 32 (40%) had an elevated TRV and, of those who underwent right heart catheterization, 8 (10% of the total population) had PH.⁸⁸ In a third large screening study of 398 patients with sickle cell disease in France using right heart catheterization,⁹¹ 6% were shown to have

PH. Of note, the French study excluded approximately 10% of patients, those with “severe” renal, liver, or lung disease, with severity defined as a creatinine clearance of less than 30 mL/min, an abnormal prothrombin time (international normalized ratio > 1.7), and chronic restrictive lung disease defined by a TLC of less than 70% predicted. It is not clear why these patients would be excluded from a prevalence study of sickle cell disease–related PH, especially considering the fact that all of these complications develop as a direct consequence of sickle cell disease and all three represent significant published risk factors for developing PH in sickle cell disease.

Mortality. An elevated pulmonary artery pressure increases the risk of death for patients with sickle cell disease. In the NIH study, compared with patients with TRV less than 2.5 m/sec, the rate ratios for death for TRVs of 2.5 to 2.9 m/sec and greater than 3.0 m/sec were 4.4 and 10.6, respectively.²⁹ In support of these findings, De Castro and colleagues⁷⁹ found that 6 of 42 patients (14%) with PH and only 2 of 83 patients (2%) without this finding died during a 2-year follow-up period. Similarly, in the study by Ataga and colleagues,⁷⁸ 9 of 36 patients with PH and only 1 of 57 patients without PH died during the 2.5-year follow-up period (relative risk, 9.3). Consistent with these data, in a cohort of 632 patients with SCD from the United States and England, 11.2% had TRV \geq 3.0 m/sec and 24.1% had NT-proBNP level \geq 160 pg/mL. Of 22 deaths during follow-up, 50% had a TRV \geq 3.0 m/sec. At 24 months, the cumulative survival was 83% with TRV \geq 3.0 m/sec and 98% with TRV < 3.0 m/sec. The hrs for death were 11.1 (95% CI 4.1–30.1; $p < 0.0001$) for TRV \geq 3.0 m/sec, 4.6 (1.8–11.3; $p = 0.001$) for NT-proBNP \geq 160 pg/mL, and 14.9 (5.5–39.9; $p < 0.0001$) for both TRV \geq 3.0 m/sec and NT-proBNP \geq 160 pg/mL.^{91a}

When documented by right heart catheterization, the presence of PH is a major risk factor for death in patients with sickle cell disease. Castro and colleagues⁹² reported a 50% two-year mortality rate in patients with PH; with each increase of 10 mm Hg in PAP, there was a 1.7-fold increase in the rate of death. In the NIH study, the mortality rate was significantly higher in the PH group (20 deaths, 36%) than in either the group without PH by right heart catheterization (3 deaths, 10%), or the general sickle cell group with normal Doppler echocardiographic estimates of pulmonary artery systolic pressure (50 deaths, 13%).⁹⁰ Similarly, in both the Brazilian⁸⁸ and French⁹¹ cohorts, the mortality rate was significantly higher in the PH group (38% and 23%, respectively) than in the other patients. In the NIH study, specific hemodynamic variables were independently and significantly related to mortality, including PAP, diastolic PAP, systolic PAP–pulmonary capillary wedge pressure, transpulmonary gradient, and pulmonary vascular resistance.⁸⁹ These data suggest that mortality in adults with sickle cell disease and PH is proportional to the physiologic severity of pulmonary vascular disease.

Pathogenesis. Epidemiologic studies suggest that the central risk factor for the development of PH in patients with sickle cell disease is the severity of hemolytic anemia (Fig. 94-4).^{29,78,79,93} The association between the development of PH and the intensity of hemolytic anemia has been

Figure 94-4 Multifactorial pathogenesis of pulmonary hypertension in sickle cell disease, focusing on changes at a small pulmonary artery. PH is thought to arise from multifactorial effects of hemolysis, as well as from the anemia leading to increased cardiac output and multiorgan damage from iron overload, renal failure, and asplenia. EPO, erythropoietin; ET-1, endothelin-1; HIF, hypoxia inducible factor; NO, nitric oxide; PS, phosphatidylserine; Q, cardiac output; TF, tissue factor; VEGF, vascular endothelial growth factor.

observed in three prospective screening studies of adult patients with sickle cell disease.^{29,78,79} in an expanding number of pediatric studies,^{83–85,94,95} and in studies using right heart catheterization to define PH.^{88–90} This suggests that hemolysis is related mechanistically to PH. That relationship is plausible and biologically significant because free hemoglobin inactivates the intrinsic vasodilator NO.^{14,28} Hemolysis also releases arginase, which depletes L-arginine, the substrate for NO synthesis.²⁷ These combined mechanisms result in a state of decreased NO bioavailability and “resistance” to NO-dependent vasodilation.¹⁴

Hemolysis and decreased NO bioavailability also induce platelet activation,⁹⁶ thrombin generation, and tissue factor activation.⁹⁷ There is also a correlation between the rate of hemolysis and the levels of procoagulant factors in blood in patients with sickle cell disease.^{98–100} Hemolysis is also associated with the formation of red blood cell microvesicles expressing phosphatidylserine, which activates tissue factor.^{100,101} These factors all contribute to an increased risk of thrombosis. In addition, sickle cell patients with functional asplenia and thalassemia patients with surgical

splenectomy have increased levels of cell-free hemoglobin and red cell microvesicles, providing a potential mechanism for the hypercoagulability associated with both diseases, with possible exacerbation by asplenia.¹⁰⁰ Finally, the accumulation of redox-active heme and iron from lysed red blood cells further contributes to the generation of reactive oxygen species that can exacerbate ischemia-reperfusion injury, thrombosis, and vascular proliferative responses.¹⁰² Another downstream effect of hemolytic anemia includes increased endothelin-1-mediated vasoconstrictive and proliferative responses. In patients with sickle cell disease, both at steady state and during vaso-occlusive pain crises, plasma endothelin-1 levels are increased.¹⁰³ In vitro, sickled erythrocytes increase endothelin-1 production by cultured human endothelial cells. All told, hemolysis acts via multiple mechanisms to block NO-induced vasodilation, activate procoagulant activity, injure endothelial cells, and exacerbate vasoconstriction and proliferation.

Functional or surgical asplenia could also contribute to the development of PH in patients with sickle cell disease. Splenectomy has been reported to be a risk factor for the development of PH,¹⁰⁴ particularly in patients with hemolytic disorders.¹⁰⁵⁻¹⁰⁷ Loss of splenic function may trigger platelet activation, promoting pulmonary microthrombosis and red cell adhesion to the endothelium.¹⁰⁸ The spleen also plays a critical function in the removal of senescent and damaged erythrocytes.^{109,110} Following splenectomy, moreover, the rate of intravascular hemolysis increases.¹⁰⁰

Historically, PH in patients with sickle cell disease was thought to derive from the repetitive episodes of pulmonary vaso-occlusive crisis and ACS leading to pulmonary fibrosis, vascular obstruction, and chronic hypoxemia. However, this association has not been supported by epidemiologic studies in which the number of episodes of vaso-occlusive crisis and ACS have not been shown to be associated with PH.^{29,80}

Clinical Features and Evaluation. The diagnostic evaluation of patients with sickle cell disease suspected of having PH should follow the same guidelines established for other causes of PH.^{111,112} Given the high prevalence of PH in this population and the associated high mortality, we recommend that all adults with sickle cell disease undergo universal noninvasive screening with Doppler echocardiography or with assessment of steady-state plasma NT-proBNP levels.^{112a} In patients with sickle cell disease, as described earlier, the echocardiographic estimation of pulmonary artery systolic pressures (where pulmonary artery systolic pressure = $4 \times \text{TRV}^2$ + estimate of the right atrial pressure) correlates reasonably well with measured pulmonary systolic pressures by right heart catheterization.^{29,113}

Although no prospective data on prevalence and risk of PH are available for children, we currently recommend that children with hypoxemia, high hemolytic rates (hemoglobin values < 7 g/dL with high LDH values), and/or recurrent ACS be screened. It is important that such screening be performed in the steady state because pulmonary pressures rise during vaso-occlusive painful crisis.¹¹⁴

The diagnosis of PH in patients with sickle cell disease can be challenging (Fig. 94-5; Videos 94-1 and 94-2). Exertional dyspnea, the most typical presentation of PH, is also a cardinal symptom of chronic anemia, and therefore a

high index of suspicion for PH is necessary. Other conditions that commonly present in patients with sickle cell disease, such as left ventricular dysfunction, pulmonary fibrosis, and liver cirrhosis, could also present in a similar fashion and result in PH. Patients with PH tend to be older and have higher systolic arterial blood pressure, lower hemoglobin levels, higher indices of hemolysis (such as high bilirubin or LDH values), lower hemoglobin oxygen saturation, greater degree of renal and liver dysfunction, and a higher number of lifetime red blood cell transfusions.²⁹ As such, the diagnostic evaluation of these patients should include an aggressive search for other conditions that might contribute to PH, such as iron overload, chronic liver disease, *human immunodeficiency virus* (HIV), nocturnal hypoxemia, and thromboembolism.

A diagnostic right heart catheterization is essential to confirm the diagnosis and exclude diastolic dysfunction (see later).⁹⁸ The 6-minute walk test is a useful surrogate for functional capacity in this patient population even considering the high prevalence of confounding factors such as the presence of avascular necrosis of the hip. Specifically, the 6-minute walk test inversely correlates with the severity of PH,¹⁰² and PH-specific therapy improves walk distance.¹⁰³

The Doppler echocardiogram is an important tool for population screening and estimation of pulmonary artery pressure, but it cannot be used to diagnose or define PH in an individual patient. For a given patient, a diagnosis of PH is based on the measurement of the mean pulmonary artery pressure via a right heart catheterization. In a single individual, the use of a TRV ≥ 2.5 m/sec has low specificity for a diagnosis of PH,⁹¹ with only 25% of patients with a TRV ≥ 2.5 m/sec having the diagnosis of PH. A TRV ≥ 2.9 m/sec has a higher positive predictive value of 64%, but high false-negative rate of 42%. Combining a TRV ≥ 2.5 m/sec, a high NT-proBNP level (>164.5 pg/mL), and a low 6-minute walk distance of less than 333 m, the positive predictive value for PH is 62%, with a false-negative rate of 7%.

Abnormal pulmonary function can be found in most patients with sickle cell disease. The pulmonary function abnormalities are characterized by mild restrictive lung disease (mean total lung capacity values of about 79% of predicted), abnormal diffusing capacity, and radiographic signs of mild pulmonary fibrosis,^{40,117-121} and the severity of these defects seems to be slightly greater in those patients with PH.¹¹⁵ However, in these patients the degree of pulmonary function abnormalities is rarely severe enough to be a major contributor to the etiology of PH.

A ventilation-perfusion scan is an indispensable component of the evaluation because chronic thromboembolic PH, if amenable to pulmonary endarterectomy, is a potential curable cause of PH reported in patients with chronic hemolytic disorders. In the majority of cases, scintigraphic evidence of thromboembolic disease is uncommon and the most commonly seen abnormality is of patchy areas of abnormal perfusion, similar to findings described in other forms of PH.^{115,122} Chronic thromboembolic PH is present in approximately 5% of sickle cell patients with severe PH,¹¹⁵ and the disease has been successfully treated surgically in two patients with sickle cell disease (Fig. 94-6).¹²³ As such, patients should undergo imaging studies and, if

suggestive of chronic thromboembolic PH, should undergo more invasive studies (i.e., angiography) to exclude this potentially surgically treatable condition.

Measurement of NT-proBNP levels can be used as a PH biomarker for diagnosis and risk stratification in patients with sickle cell disease.⁸⁰ In a contemporaneous cohort, NT-proBNP levels were higher in patients with sickle cell disease–associated PH and correlated directly with the severity of PH and the degree of functional impairment. An NT-proBNP level of 160 pg/mL or greater had a 78% positive predictive value for finding an elevated TRV and was an independent predictor of mortality. In a subset of individuals participating in the MSH follow-up study in 1996, 30% of patients had an NT-proBNP level of 160 pg/mL or greater. An NT-proBNP level of 160 pg/mL or greater in the MSH cohort was independently associated with mortality. Similarly, in patients enrolled in the CSSCD from 1978 and 1988, elevated levels of NT-proBNP were independently associated with a higher risk of death.⁸¹

In contrast to patients with traditional forms of PH (e.g., idiopathic pulmonary arterial hypertension, scleroderma associated PAH) (see Chapters 58 and 59), who are symptomatic with P_{AP}s in the range of 50 to 60 mm Hg, in patients with sickle cell disease the degree of elevation in P_{AP} is mild to moderate, in the range of 30 to 40 mm Hg, with mild elevations in pulmonary vascular resistance. These patients also have coexistent mild elevation in pulmonary capillary wedge pressure, suggesting left heart failure (Table 94-4). Right heart catheterization data from these multiple studies^{18,20-23} show that the hemodynamic etiology of the PH in patients with sickle cell disease is multifactorial: precapillary PH (defined by an P_{AP} ≥ 25 mm Hg and a wedge pressure ≤ 15 mm Hg) is present in 50% of catheterized patients, whereas pulmonary venous hypertension secondary to left ventricular diastolic dysfunction disease (defined by an P_{AP} ≥ 25 mm Hg and a wedge pressure > 15 mm Hg) is present in 50%.

Further, using echocardiography in a cohort of 141 patients with sickle cell disease, Sachdev and associates¹²⁴ found that 47% of patients had PH, diastolic dysfunction, or both (29% had PH alone, 11% had diastolic dysfunction and PH, and 7% had diastolic dysfunction alone). PH and diastolic dysfunction were associated with a relative risk of death of 5.1 and 4.8, respectively, while the relative risk of death when both were present was 12.0.¹²⁴ These data suggest that both PH and diastolic dysfunction indepen-

dently carry mortality risk. In addition, in a series of 483 patients with homozygous sickle cell disease, markers of diastolic dysfunction were independently associated with a low 6-minute walk distance.

Regardless of the hemodynamic etiology, sickle cell disease patients with chronic anemia, who maintain a high compensatory resting cardiac output in order to ensure adequate oxygen delivery, normally have a reduced pulmonary vascular resistance and appear to be poorly tolerant of even small increases in pulmonary vascular resistance. When compared with age-, gender-, and hemoglobin-matched patients with sickle cell disease without PH, individuals with PH exhibited a lower 6-minute walk distance (435 ± 31 vs. 320 ± 20 meters; *P* = 0.002), lower peak oxygen consumption on cardiopulmonary exercise testing (50 ± 3% vs. 41 ± 2% of predicted; *P* = 0.02), and higher ventilatory equivalent for CO₂ at anaerobic threshold (31.6 ± 1.5% versus 39.2 ± 1.6; *P* = 0.035) on cardiopulmonary exercise testing.¹⁰² Patients with sickle cell disease and PH appear to have worse function than is reported for patients with PH from other etiologies.¹²⁵ In addition, in patients with sickle cell disease, pulmonary artery vascular resistance sharply rises with exercise, suggesting that pulmonary vascular disease contributes to functional limitation in these patients.¹¹⁴ Taken together, these data suggest that, in sickle cell disease patients with chronic anemia, mild to moderate PH has a severe adverse impact on functional and aerobic exercise capacity.

Treatment. Data on the specific management of patients with sickle cell disease and PH are limited. Most of the recommendations are based on expert opinion or extrapolated from data derived from other forms of PH.^{125a} The general approach should include maximization of sickle cell disease–specific therapy (i.e., treatment of primary hemoglobinopathy), treatment of hypoxia with chronic oxygen therapy, treatment of associated conditions (such as iron overload, chronic liver disease, HIV infection, nocturnal hypoxemia, and thromboembolic disorders). For patients with sickle cell disease with PH (P_{AP} ≥ 25 mm Hg and wedge pressures < 15 mm Hg with a relatively high pulmonary vascular resistance, > 160 dyn•sec⁻¹•cm⁻⁵), targeted therapy with pulmonary vasodilator/antiremodeling agents can be considered (Fig. 94-7).

Because chronic intravascular hemolysis is a central mechanism in the development of PH, it is likely that optimizing sickle cell disease therapy would be beneficial through amelioration of the principal mechanism involved in the pathogenesis of PH. Hydroxyurea has been shown to decrease the incidence of pain episodes and ACS, reduce the need for transfusions, and lower overall mortality.^{41,64} It is possible that some of the decreases in pulmonary and cardiovascular deaths seen in hydroxyurea-treated patients could be related to an improvement in PH. For patients with creatinine levels less than 1 mg/dL, hydroxyurea is started at a dose of 15 mg/kg/day and titrated up to a maximum of 35 mg/kg/day. Detailed treatment guidelines have been published.^{65,126} Patients with renal dysfunction tend not to tolerate the myelosuppressant effects of hydroxyurea and, in those cases, we recommend adding erythropoietin to the regimen. Long-term transfusion therapy lowers the risk of most complications of the disease, including the risks of

Table 94-4 Hemodynamic Profiles in Patients with Sickle Cell Disease

	Without PH	With PH
P _{AP} (mm Hg)	19 ± 0.7	36 ± 1
PRA (mm Hg)	6 ± 0.4	10 ± 1
PPW (mm Hg)	11 ± 0.5	17 ± 1
CO (L/min)	10 ± 0.5	9 ± 0.3
PVR (dyn•sec ⁻¹ •cm ⁻⁵)	59 ± 6	197 ± 14

CO, cardiac output; P_{AP}, mean pulmonary artery pressure; PPW, pulmonary wedge pressure; PRA, right atrial pressure; PVR, pulmonary vascular resistance.

Data from references 76, 115, 220 except PVR, which comes from 115, 220.

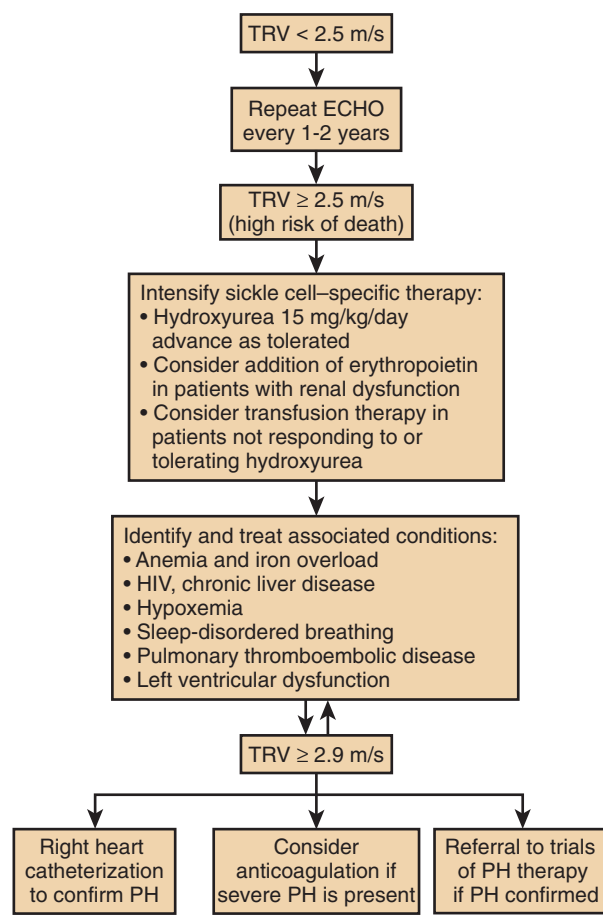

Figure 94-7 Treatment algorithm in patients with sickle cell disease and pulmonary hypertension. Depending on the echocardiographic determination of PAP by assessment of TRV, treatment is accelerated. TRV, tricuspid regurgitation velocity.

pulmonary events and central nervous system vasculopathy,¹²⁷⁻¹²⁹ and might improve cardiopulmonary function and prevent the progression of PH.

The potential benefits of warfarin therapy observed in patients with idiopathic pulmonary arterial hypertension (Group 1, see Chapter 58) have to be weighed against the risk of hemorrhagic stroke in adults with sickle cell disease or hemorrhage in chronically anemic individuals. We believe that the relatively low risk of hemorrhagic stroke (0.21 events per 100 patient-years¹³¹) compared with the high risk of death in patients with severe PH supports anticoagulation in patients without a specific contraindication who have hemodynamic evidence of PH or chronic thromboembolic PH.

There are no long-term data on the specific treatment of PH in sickle cell disease, and the choice of agents is largely empirical and based on the safety profile of the drugs and physician preference. However, there are specific treatment concerns regarding the use of these drugs in patients with hemolytic diseases. The use of prostanoids can produce systemic vasodilation and increases in cardiac output, raising the concern for the potential development of high-output heart failure in anemic patients. In addition, the risk of chronic intravenous-line-related complications such as thrombosis and sepsis is likely higher in patients with sickle

cell disease. The main toxicity of endothelin-1 receptor antagonists is hepatocellular injury, which could limit their applicability in patients with sickle cell disease at risk for liver dysfunction (e.g., iron overload, hepatitis C). Another class effect of these agents is a dose-related decrease in hemoglobin levels, usually by approximately 1 g/dL.¹²⁵ The main concern related to the use of sildenafil is the potential for the development of priapism in men with sickle cell disease.

Sildenafil functions by inhibiting the metabolism of cyclic guanosine monophosphate, the second messenger that mediates the effects of NO. In a series of seven patients with either thalassemia or sickle-thalassemia and severe PH, treatment with sildenafil from 4 weeks to 48 months resulted in an improvement in TRV, New York Heart Association functional class, and 6-minute walk distance.¹³² In another case series of 12 patients with sickle cell disease treated with sildenafil for a mean of 6 months, mean pulmonary artery systolic pressure decreased by 9 mm Hg, 6-minute walk distance improved by 78 m, and mean NT-proBNP decreased by 448 pg/mL.¹¹⁶

The published experience with endothelin antagonists in the treatment of PH is also limited. Minniti and colleagues¹³³ reported on the use of bosentan and ambrisentan in a cohort of 14 patients with sickle cell disease and PH documented by right heart catheterization. Endothelin antagonist therapy either as monotherapy or in combination with sildenafil was well tolerated and resulted in a modest improvement in 6-minute walk distance (baseline 357 ± 22 vs. 398 ± 18 m 6 months post therapy). There are no published case series of prostanoid therapy in this population.

Randomized multicenter placebo-controlled studies evaluating the role of PH therapy in patients with sickle cell disease have not yet provided clear guidance. In the ASSET-1 and ASSET-2 studies of bosentan versus placebo, insufficient recruitment led to early termination of the studies. In the limited sample of patients, bosentan was well tolerated with no significant differences in serious adverse events or abnormal laboratory tests, but efficacy end points could not be formally analyzed.¹³⁴ The Walk-PHaSST (Pulmonary Hypertension and Sickle Cell Disease with Sildenafil Therapy) evaluated the safety and efficacy of oral sildenafil for the treatment of Doppler-defined PH (tricuspid regurgitant jet velocity ≥ 2.7 m/sec) in adults and children (older than 12) with sickle cell disease.¹³⁵ After 74 (out of a planned 132) subjects were enrolled, the study was discontinued due to a significant increase in hospitalizations caused by vaso-occlusive pain crises in the sildenafil arm (45% sildenafil, 22% placebo). Subject hospitalization for pain was the predominant cause for this difference. Although underpowered at the time the study was stopped, there was no evidence of a treatment effect on 6-minute walk distance or NT-proBNP. In that study, patients were not required to be on hydroxyurea and/or chronic transfusion therapy for sickle cell disease. Thus, it is uncertain whether these adverse effects could be mitigated by intensification of sickle cell disease-specific therapy before the initiation of sildenafil treatment. A case of severe pulmonary arterial hypertension related to pulmonary veno-occlusive disease has been reported in a patient with SCD. This patient failed medical therapy and underwent a successful bilateral lung transplantation.^{135a}

Figure 94-8 Pulmonary fibrosis complicating multiple episodes of acute chest syndrome. Bibasilar (right greater than left) reticular opacities (arrows) are seen in the chest radiograph.

Chronic Lung Disease

Sickle cell chronic lung disease has been used as a wastebasket term to encompass pulmonary fibrosis resulting from recurrent ACS and PH.⁴⁰ Our current understanding of sickle cell chronic lung disease suggests that pulmonary fibrosis is quite mild, and that PH is a more important cause of chronic pulmonary disease. For this reason, we feel that this older terminology should be replaced with a more specific diagnostic classification.

In patients with sickle cell disease, repetitive episodes of *acute lung injury* (ALI) related to ACS can result in parenchymal damage and typically mild restrictive lung disease (Fig. 94-8). In a study of 310 patients with homozygous sickle cell disease, pulmonary function was abnormal in 90% of adult patients; the most common abnormalities included mild restrictive physiology and decreased diffusing capacity.¹³⁶ These abnormalities worsen with age and are associated with increases in pulmonary artery pressures.^{115,136} In contrast, airway hyperactivity is much more common in children.¹³⁷ Data are conflicting on whether children with sickle cell disease have a much higher prevalence of asthma and airway hyperactivity, when compared with ethnically and aged-matched controls.^{47,138} It is increasingly apparent that children with asthma appear to have a higher incidence of ACS, cerebral vascular accidents, and need for blood transfusions, arguing for aggressive diagnosis and treatment of asthma in this population.^{47,48,139}

Sleep-disordered breathing has been reported in both children and adults with sickle cell disease. In children, sleep-related upper airway obstruction and hypoxemia are the most common disturbances. In an uncontrolled study, adenotonsillectomy led to symptomatic improvement and amelioration of oxygen desaturation.^{140,141} Several lines of evidence suggest that nocturnal hypoxemia contributes to the development of neurologic events and

vaso-occlusive crisis via mechanisms that could involve up-regulation of several inflammatory endothelial cell adhesion molecules.¹⁴²⁻¹⁴⁴

THALASSEMIA

Thalassemia refers to a spectrum of diseases characterized by reduced or absent production of one or more α or β globin chains. β -Thalassemia results from impaired production of β globin chains, which leads to a relative excess of α globin chains.¹⁴⁵ These excess α globin chains are unstable, incapable of forming soluble tetramers on their own, and precipitate within the cell, leading to ineffective erythropoiesis and hemolytic anemia.¹⁴⁵ Thalassemia major, or homozygous β -thalassemia, is a severe disorder due to the inheritance of two β -thalassemia alleles. Starting during the first year of life, patients develop severe and lifelong transfusion-dependent anemia, hepatosplenomegaly, and skeletal deformities due to bone marrow expansion; they are prone to infection and skeletal fractures.

β -Thalassemia minor, also called β -thalassemia trait, arises in heterozygotes who have inherited a single gene leading to reduced β globin chain production. Such patients are asymptomatic, may be only mildly anemic, and are usually discovered when a blood count has been obtained for other reasons. β -Thalassemia intermedia is seen in patients with disease of intermediate severity, such as those who are compound heterozygotes of two thalassemic variants. Such patients may have the skeletal abnormalities and hepatosplenomegaly seen in thalassemia major. However, their hemoglobin concentrations usually range from 5 to 10 g/dL and they usually require transfusions only when they have an intercurrent event, such as an infection, that impairs erythropoiesis. Their clinical symptoms may not be apparent until well after the first year of life. Hemoglobin E, which has a point mutation in the β globin gene, is the most common hemoglobin variant in the world. In the heterozygous or homozygous states, it is mostly asymptomatic or associated with a mild microcytic anemia. When hemoglobin E is present along with β -thalassemia, the condition is called hemoglobin E-thalassemia; about half of these patients are phenotypically similar to patients with thalassemia major and require regular transfusion therapy, with the other half having courses similar to patients with thalassemia intermedia.

Several cardiopulmonary abnormalities arise in patients with β -thalassemia, including restrictive and obstructive defects, hyperinflation, abnormal diffusing capacity, and decreases in aerobic exercise capacity.¹⁴⁶⁻¹⁴⁸ However, in the majority of cases, these pulmonary function abnormalities are not associated with clinical symptoms. Several of the clinical complications related to thalassemia are related to complications of therapy such as transfusion-related iron overload, infection, thrombosis, possibly acute deterioration in pulmonary function associated with the use of the iron chelator deferoxamine, and PH related to splenectomy. In patients who are poorly transfused, extramedullary erythropoiesis can rarely cause pulmonary parenchymal masses, mediastinal masses (see eFigs. 83-44 and 83-45, and pleural effusions.

Similar to sickle cell disease, PH is a common complication of thalassemia. Approximately 40% to 50% of patients

with thalassemia intermedia¹⁴⁹ and 10% to 75% of patients with thalassemia major have echocardiographic evidence of PH.¹⁵⁰⁻¹⁵² In a multicenter cross-sectional study of 1309 Italian β -thalassemia patients, patients with a tricuspid-valve regurgitant jet velocity ≥ 3.2 m/s (3.6% of the population) on transthoracic echocardiography underwent right heart catheterization to confirm the diagnosis of PH (defined as mean pulmonary arterial pressure ≥ 25 mm Hg and pulmonary capillary wedge pressure ≤ 15 mm Hg). The prevalence of PH on right heart catheterization was 2.1% (4.8% in patients with thalassemia intermedia and 1.1% in patients with thalassemia major).^{152a} In spite of its potential complications, chronic transfusion therapy in severe thalassemia has changed the clinical course of the disease and is likely to have a favorable impact in individuals with PH. This idea is supported by a report that, in well-transfused, iron-chelated patients with thalassemia major, PH was completely prevented.¹⁵³ A favorable response to sildenafil has been reported in patients with thalassemia major and intermedia.^{132,154} In a recent open-label study of 10 patients with β -thalassemia and a TRV > 2.5 m/sec on Doppler echocardiography (none of the patients underwent confirmatory right heart catheterization), treatment with sildenafil resulted in a significant decrease in TRV and improved left ventricular end-systolic/diastolic volume but did not improve 6-minute walk distance.¹⁵⁵ There are also case reports of favorable response to bosentan¹⁵⁶ and epoprostenol¹⁵⁷ in patients with right heart catheterization-confirmed precapillary PH. To date, however, there are no studies evaluating either the specific hemodynamic derangements associated with PH or the impact of PH on survival in this patient population.

OTHER HEMOGLOBIN DISORDERS

Hemoglobin gene mutations can result in functional abnormalities in the globin chains that alter gas ligand affinity and alter oxygen uptake and delivery. Remarkably, there are more than 120 human hemoglobin gene mutations that have been associated with abnormal hemoglobin oxygen affinity.¹⁵⁸ Patients with moderately high-affinity hemoglobins usually present with erythrocytosis and are typically asymptomatic, but patients with variants associated with high oxygen affinity can present with cyanosis or symptoms related to increased red blood cell mass (polycythemia). In addition, whereas patients with low oxygen affinity hemoglobin variants are usually asymptomatic, some can present with cyanosis. The initial step in the workup of patients suspected of having a hemoglobinopathy affecting oxygen affinity is to evaluate the red cell oxygen equilibrium curve, whereby both the oxygen saturation of hemoglobin and partial pressure of oxygen are directly measured to obtain a p50, the partial pressure of oxygen at which hemoglobin is 50% saturated. This approach should obviate the need for unnecessary and potentially invasive diagnostic procedures.

Methemoglobin is a nonfunctional state of hemoglobin in which the irons of heme are oxidized to the ferric (Fe^{3+}) state and are unable to bind oxygen. In addition, the oxygen affinity of any accompanying ferrous hemes in the hemoglobin tetramer is increased so that the oxygen dissociation curve is “left shifted” and oxygen delivery to the tissues is

impaired.¹⁵⁹ Three mechanisms are associated with the development of methemoglobinemia: a genetic mutation resulting in abnormal hemoglobin (hemoglobin M), a congenital deficiency of methemoglobin reductase enzyme (cytochrome b_5 or cytochrome- b_5 reductase deficiency), and a drug/toxin-induced oxidation of hemoglobin. Most individuals with congenital methemoglobinemia are asymptomatic, and their primary complaint is “cyanosis” presenting as a slate-blue color of the skin and mucous membranes.

Cyanosis is clinically apparent when the absolute concentration of methemoglobin exceeds 1.5 g/dL, equivalent to approximately 10% methemoglobin.¹⁶⁰ In cases associated with drugs and toxins, the severity of the methemoglobinemia depends on the dose of the agent and the individual's susceptibility. At methemoglobin levels greater than 35%, patients can complain of headaches, weakness, and dyspnea; levels greater than 80% are typically incompatible with life.¹⁵⁸ Symptomatic patients should be treated with methylene blue given intravenously at a dose of 1 to 2 mg/kg, which acts as a cofactor for the enzyme NADPH methemoglobin reductase. Electrons are transferred from NADPH to methylene blue, which leads to a reduction of the heme iron, in the form of deoxyhemoglobin.¹⁶¹ Methylene blue should not be administered to individuals with glucose-6-phosphate dehydrogenase deficiency because it may precipitate hemolysis.¹⁶²

Carbon monoxide (CO) binds to hemoglobin to form *carboxyhemoglobin* (COHb). CO has a much greater affinity than oxygen for hemoglobin. The binding of CO to heme creates an allosteric change that diminishes the ability of hemoglobin to release oxygen to peripheral tissues, resulting in impaired oxygen transport and utilization. As such, CO poisoning is a major cause of morbidity and mortality. The clinical effects of CO poisoning are nonspecific and easily confused with other illnesses, such as viral illness, benign headache, and various cardiovascular and neurologic syndromes.¹⁶³ As the severity of exposure increases, patients develop more pronounced symptoms, with oxygen-dependent organs (the brain and the heart) showing the earliest signs of injury. Oxygen therapy improves tissue hypoxia and accelerates elimination of CO. Hyperbaric oxygen therapy should be considered in patients with severe CO poisoning (e.g., COHb $> 25\%$, evidence of tissue ischemia and loss of consciousness) and may reduce the incidence of the late neurocognitive deficits associated with severe CO intoxication.^{164,165}

Cyanide binds the ferric ion (Fe^{3+}) of cytochrome oxidase a3, inhibiting this final enzyme in the mitochondrial cytochrome complex and thereby preventing oxygen utilization by tissues. A small amount of cyanide can also bind to the ferrous (Fe^{2+}) iron of hemoglobin to form cyanhemoglobin, which is unable to transport oxygen and thus further exacerbates tissue hypoxia.¹⁶⁶

WHITE BLOOD CELL DISORDERS

LEUKEMIAS

Although the majority of clinical pulmonary manifestations in patients with leukemia are not related to the disease

Figure 94-9 Leukemic infiltrates in a patient with chronic lymphocytic leukemia. **A**, Diffuse nodular opacities (arrows). **B**, Transbronchial biopsy specimen demonstrating diffuse infiltration of lung interstitium by leukemic cells (especially between arrows). (H&E stain).

itself, autopsy studies show that thoracic involvement is common in all leukemia types. Overall, the most common finding is mediastinal and lymph node involvement, but pleural and pulmonary infiltration is found in 20% to 65% of autopsy series.¹⁶⁷⁻¹⁶⁹

The mediastinum is the most commonly affected intrathoracic site. This is often manifest as a focal mass (eFig. 94-4) or as generalized mediastinal involvement. Hilar adenopathy is seen in 15% to 25% of patients.^{170,171} Pleural effusion, usually unilateral, can present in up to 25% of cases and is seen more frequently in myeloid leukemias.¹⁷² In the majority of cases, the effusion is related to lymphatic obstruction, congestive heart failure, or infections, with only approximately 5% of cases caused by leukemic infiltration.¹⁷²

Leukemic pulmonary infiltrates are clinically significant in approximately 10% of patients (Fig. 94-9).¹⁶⁷ The usual radiographic pattern of involvement is a bilateral reticular pattern with septal lines resembling interstitial edema or lymphangitic carcinomatosis (eFig. 94-5). Interlobular smooth or nodular septal thickening is the most common high-resolution CT finding, followed by thickening of bronchovascular bundles. Other manifestations include peribronchovascular or random nodules, which can coalesce into masslike consolidation, focal areas of air space disease, and ground-glass opacities.¹⁷²⁻¹⁷⁵ The diagnosis of leukemic infiltrates is one of exclusion because most of the pulmonary parenchymal abnormalities in these patients are associated with processes other than the hematologic disease, such as infections, hemorrhage, or pulmonary edema.

Pulmonary leukostasis or hyperleukocytosis is characterized by the distention of small pulmonary vessels by leukemic blast cells. It is most commonly seen in patients with acute leukemias and white blood cell counts greater than 100,000 cells/ μ L with a predominance of blast cells.¹⁷⁶ Clinical and radiographic findings include dyspnea and hypoxemia associated with a bilateral reticular pattern with septal lines or air space consolidation.^{176,177} Symptomatic leukostasis is a medical emergency, and efforts should be made to lower the white blood cell count rapidly. In most patients, rapid cytoreduction can be achieved by chemotherapy, but leukapheresis should be considered in severe cases or in patients who cannot receive chemotherapy immediately. Finally, patients can present with acute spurious hypoxemia caused by an ex vivo decrease in arterial PO_2 mediated by the enhanced metabolism of the malignant cells; this process has been referred to as “leukocyte larceny.”

Pulse oximetry provides an accurate assessment of arterial oxygen saturation in such circumstances.

Leukemic cell lysis pneumopathy arises in patients with high leukocyte counts undergoing chemotherapy and is part of the spectrum of tumor lysis syndrome. Severe hypoxia and diffuse bilateral opacities develop within 48 hours after the initiation of chemotherapy, resembling the clinical and pathologic presentation of ARDS.¹⁷⁸ In patients at intermediate or high risk for the development of tumor lysis syndrome, preventive measures are recommended such as aggressive intravenous hydration, urine alkalinization in selected patients, and the use of agents to decrease uric acid levels such as allopurinol and rasburicase.¹⁷⁹ These therapeutic strategies also apply to patients with established tumor lysis syndrome.

PLASMA CELL DISORDERS

Thoracic involvement in multiple myeloma is common, seen in 46% of patients, with the majority of cases related to neoplastic infiltration of the skeleton.¹⁸⁰ Pleural effusion caused by malignant infiltration has been reported, and for unclear reasons the effusion appears to involve the left lung more frequently.¹⁸¹ Pulmonary parenchymal or airway involvement is also rare, taking the form of single or multiple masses, diffuse parenchymal opacities, or endobronchial lesions.¹⁸⁰ Pulmonary amyloidosis can also result from systemic amyloid deposition (eFig. 94-6).¹⁸²

Plasmacytoma is a circumscribed proliferation of plasma cells not associated with a plasma cell disorder. The vast majority of plasmacytomas involving the respiratory tract arise in the pharynx, followed by the trachea and, much less commonly, the lower airways and the pulmonary parenchyma.^{183,184} Pulmonary parenchymal plasmacytomas present as a nodule or mass that is indistinguishable from bronchogenic carcinoma and may rarely present as a chest wall (eFigs. 94-7 and 94-8) or mediastinal (eFig. 94-9) mass.

THROMBOSIS AND DISORDERS OF COAGULATION

INHERITED THROMBOPHILIA

Inherited thrombophilia encompasses the various mutations associated with venous thromboembolism. The most

Table 94-5 Inherited Thrombophilic Disorders

Disorder	Prevalence in Healthy Individuals (%)	Frequency in Patients with VTE (%)	Relative Risk of First Episode of DVT	Relative Risk of Recurrence
Factor V Leiden (heterozygous)	0.05–4.8	18.8	7	1.4
Factor V Leiden (homozygous)	0.02	1.5	80	n/a
Prothrombin G20210A allele	0.06–2.7	7.1	2.8	1.7
Protein C deficiency	0.2–0.4	3.7	6.5	1.8
Protein S deficiency	0.16–0.21	2.3	5.0	1.0
Antithrombin III deficiency	0.02	1.9	20	2.6
Hyperhomocysteinemia	5–7	10	3.0	0.9

DVT, deep venous thrombosis; VTE, venous thromboembolism.

Adapted from Whitlatch NL, Ortel TL: Thrombophilias: when should we test and how does it help? *Semin Respir Crit Care Med* 29:25–39, 2008; and Dalen JE: Should patients with venous thromboembolism be screened for thrombophilia? *Am J Med* 121:458–463, 2008.

frequent causes of an inherited thrombophilia are the factor V Leiden mutation and a prothrombin gene (*G20210A*) mutation, which together account for 50% to 60% of cases. Mutations in the genes coding for protein S, protein C, and antithrombin account for most of the remaining cases, while dysfibrinogenemias are rare causes of hypercoagulability (Table 94-5).^{185,186} Patients with these disorders usually present with recurrent thromboembolism at a young age, typically younger than 50 (see also Chapter 57).

Several of these disorders are associated with an increased risk of initial and recurrent thromboembolism (see Table 94-5). There is, however, controversy about whether screening of individuals with venous thromboembolism for the presence of these inherited defects is warranted. Expert opinion suggests that evaluation for inherited thrombophilic disorders should be pursued in individuals presenting with idiopathic thrombosis who are younger than 50, with a history of recurrent thrombosis, or with thrombosis in an unusual site; in those with a first-degree relative with thrombosis at a young age; or in women with thrombotic events during pregnancy or while taking oral contraceptives.¹⁸⁷⁻¹⁸⁸ These recommendations must be contrasted with the results of epidemiologic studies suggesting that a thrombophilic workup after a first thrombotic event is unlikely to confer clinical benefit.¹⁹⁰⁻¹⁹² The presence of a thrombophilic disorder does not impact the acute management of a thromboembolic event but could have an impact on the duration of chronic anticoagulant therapy.¹⁹³ Patients with antithrombin, protein C, or protein S deficiency should be considered for lifelong anticoagulation. Patients with heterozygous factor V Leiden or prothrombin gene mutations generally do not need lifelong anticoagulation but will likely benefit from extended anticoagulant therapy to reduce the risk of recurrence, as shown in other patients with idiopathic thromboembolism.^{194,195} Patients with more than one allelic abnormality should also be considered for lifelong anticoagulation.

COAGULOPATHIES AND PLATELET DISORDERS

Spontaneous pulmonary hemorrhage does not appear to be a common complication of disorders of coagulation such as the hemophilias, von Willebrand disease, or thrombocytopenia. The risk of bleeding appears to increase in individuals with preexisting pulmonary lesions or after physical or procedural trauma to the respiratory system.

However, episodes of pulmonary hemorrhage, hemomediastinum, and tracheal and pleural hematomas have been described in patients with hemophilias.¹⁹⁶ Radiographic abnormalities such as scarring, fibrosis, pleural thickening, abnormalities in pulmonary vessels, and hyperinflation and cases of PH have also been described in patients with hemophilia.¹⁵⁸

COMPLICATIONS OF TRANSFUSION

TRANSFUSION-ASSOCIATED ACUTE LUNG INJURY

Transfusion-related acute lung injury (TRALI) is an acute lung injury syndrome resulting from the transfusion of blood products containing plasma, most commonly whole blood, fresh frozen plasma, platelets, and packed red blood cells. TRALI is currently the leading cause of transfusion-related morbidity and mortality.¹⁹⁷ TRALI is defined as the acute onset of hypoxemia ($PO_2/FiO_2 < 300$ mm Hg) and the appearance of new chest radiographic opacities, without evidence of elevated left atrial pressure, within 6 hours of infusion of a blood product.¹⁹⁸

Epidemiology

The incidence of TRALI is not well established but appears to be one episode for every 5000 blood component transfusions.¹⁹⁹ This likely underestimates the true incidence of the disease. Studies using systematic methods to identify TRALI cases suggest that the incidence can be 5 to 50 times higher than previously thought.²⁰⁰⁻²⁰³ A 2012 TRALI study group determined the incidence of TRALI by prospective, active surveillance in a case-control design in two academic medical centers.²⁰⁴ The annual TRALI incidence decreased from 2.6 per 10,000 units transfused in 2006 to 0.8 per 10,000 units transfused in 2009, most likely related to TRALI mitigation strategies implemented in these centers.

TRALI has been reported in all age groups and with equal incidence in men and women. A single-center study suggested that patients with hematologic malignancies or cardiovascular disease requiring cardiopulmonary bypass operations are at a higher risk of developing this complication.²⁰⁰ Administration of fresh frozen plasma, prolonged storage of blood products, and acute underlying conditions

such as recent surgery, massive transfusion, cytokine therapy, sepsis, and thrombocytopenia have also been implicated as risk factors for TRALI.^{200,202,205-209} Multiparous women are the donors most commonly associated with cases of TRALI, which probably reflects the role of the antibodies formed due to exposure to paternal leukocyte antigens during pregnancy (see next section on pathogenesis).^{199,210,211}

In the recent TRALI study group report, risk factors for transfusion recipients identified by multivariate analysis included higher IL-8 levels, liver surgery, chronic alcohol abuse, shock, higher peak airway pressure on mechanical ventilation, current smoking, and positive fluid balance. Transfusion risk factors were receipt of plasma or whole blood from female donors, volume of HLA class II antibody with normalized background ratio more than 27.5, and volume of anti-human neutrophil antigen positive by granulocyte immunofluorescence test. Little or no risk was associated with older red blood cell units, noncognate or weak cognate class II antibody, or class I antibody.²⁰⁴

Pathogenesis

Two leading hypotheses have been put forth to explain the mechanisms underlying the pathogenesis of TRALI. One theory proposes that transfused leukocyte antigens interact with antibodies to cause granulocyte activation and lung injury. An alternative “two-hit” hypothesis proposes that active substances accumulate as the blood product is stored and are transferred to a susceptible host, priming granulocytes that then secondarily produce lung injury in the setting of systemic inflammation from another insult such as sepsis.

The antileukocyte antibody hypothesis has support from several lines of evidence. Antileukocyte antibodies are found in donors or recipients after clinical episodes of TRALI, and infusion of antileukocyte antibodies in animals causes a similar form of lung injury.^{212,213} In three case reports, TRALI was produced in healthy volunteers by infusions of plasma containing strong leukocyte antibodies.²¹⁴ Antibodies against HLA class I and II antigens and HNA-3a antigens are also found in patients with TRALI.²¹⁵

The other “two-hit” hypothesis is also supported by several studies. The age of transfused blood has been reported as a risk factor for multiorgan failure in trauma patients.²¹⁶ The presence of bioactive lipids implicated in the pathogenesis of lung injury, such as lysophosphatidyl choline, is higher in blood products given to patients who develop TRALI.^{202,208} CD40 ligand, which induces injury to activated microvascular endothelial cells, accumulates in stored blood products, and significantly higher levels have been found in blood products given to patients who develop TRALI.²¹⁷

Clinical Features and Evaluation

Patients typically present with the sudden onset of respiratory distress 1 to 2 hours after the transfusion of blood products. Clinical signs include fever, tachypnea, tachycardia, and occasionally hypotension.²⁰⁶ The patients may cough pink frothy secretions with a high albumin content indicative of increased permeability (noncardiogenic) pulmonary edema. Chest radiography (see eFigs. 71-25, 71-26A) classically reveals bilateral alveolar opacities with a

normal cardiac silhouette and without pleural effusion. The finding of granulocyte, leukoagglutinating, or lymphotoxic antibodies in the serum from either the donor or recipient supports the diagnosis of TRALI, but these abnormalities are not found in all patients. The main differential diagnosis in these patients is transfusion-associated circulatory overload, and the differentiation of these two conditions can be difficult. The measurement of brain natriuretic peptide levels has been described as a helpful tool to differentiate these two entities.²¹⁸

Approximately 70% of patients require mechanical ventilation at the time of presentation.²¹⁵ The illness tends to resolve rapidly, within the first 48 hours, and with few exceptions, chest radiographs typically return to normal in 4 days. The estimated mortality associated with TRALI is 5%.²¹⁵

Treatment

Because patients usually improve spontaneously, the management of TRALI is supportive. In patients requiring mechanical ventilation, the approach should be the same as recommended for patients with ARDS. There is no convincing evidence to support the use of corticosteroids in patients with TRALI. Individuals developing TRALI should not receive further blood products from the implicated donor but do not appear to be at increased risk for recurrent episodes with products from other donors.²¹⁹ Finally, in the TRALI study group case-control study, the incidence of TRALI decreased after the reduction of transfusion of plasma from female donors.²⁰⁴

Key Points

- Primary polycythemia is caused by either an acquired or inherited genetic abnormality; secondary polycythemia is mainly related to excess erythropoietin production from chronic hypoxia.
- The acute chest syndrome and pulmonary hypertension are leading causes of recurrent disability and premature death in sickle cell disease. Acute chest syndrome is thought to result from infection, bone marrow fat embolization, and/or direct red cell intravascular sequestration causing lung injury and infarction. Pulmonary hypertension is now thought to result from hemolysis that alters nitric oxide activity and endothelial function.
- Thalassemia major is a severe heritable lifelong, multisystem disease owing to the presence of two β -thalassemia alleles; by contrast, thalassemia minor patients inherit just a single gene and may be asymptomatic with only mild anemia.
- Leukemias and plasma cell disorders involve the pulmonary parenchyma uncommonly, although mediastinal involvement, lymphadenopathy, and pleural infiltration are common at autopsy.
- There is controversy about whether screening of individuals with venous thromboembolism for the presence of inherited thrombophilic defects is warranted; criteria for diagnosis have been suggested, but epidemiologic studies show little clinical benefit. Optimal chronic management of patients with inherited thrombophilia is not well established.

- Transfusion-related acute lung injury is the leading cause of transfusion-related morbidity and mortality. Several risk factors have been identified and multiple causes may play a role. The overall incidence appears to be diminishing and clinical management remains supportive.

THYROID DISORDERS

Hyperthyroidism
Hypothyroidism

PARATHYROID DISEASES

ADRENAL DISEASES
ACROMEGALY

INTRODUCTION

Common endocrine disorders may affect the respiratory system in a variety of ways, from an increased risk of specific infections in patients with diabetes to upper airway compression in patients with goiter. There have been many studies of pulmonary physiology in patients with endocrine disorders, some of which have revealed clinically significant functional abnormalities. In other studies, however, physiologic abnormalities have not translated into clinical dysfunction, but they have helped add to our understanding of lung parenchymal growth and development, response to extrathoracic influences, and perhaps even aging. This chapter reviews the effects of various endocrine abnormalities on the pulmonary system.

DIABETES MELLITUS

The prevalence of diabetes is continuing to soar; in 2012, 29.8 million Americans, or 9.3% of the population, were diabetic.¹ The obesity epidemic appears to have largely driven the substantial increase in the prevalence of type 2 diabetes (the most common subset of diabetes mellitus) in recent decades. In addition to genetic predisposition, obesity, and other factors such as diet and inflammatory mediators, active cigarette smoking is associated with the development of insulin resistance and type 2 diabetes.²⁻⁴ The reason for this association has yet to be elucidated, although nicotinic acetylcholine receptors are expressed on pancreatic islet cells⁵ and nicotine exposure has been associated with beta cell dysfunction and increased beta cell apoptosis.⁶ Although less dramatic, there has also been an increase in the incidence of type 1 diabetes mellitus in the United States and worldwide.^{7,8} Type 1 diabetes results from autoimmune destruction of pancreatic beta cells in genetically susceptible patients, most likely triggered by environmental agents. The genetic basis of autoimmune type 1 diabetes has now been largely determined, and there are some shared genetic associations with known atopy-related traits.⁹

The relationship between asthma and diabetes is less clear. Asthma, diabetes, and obesity are common, complex disorders for which the prevalence among youth has increased since the 1990s. In a large observational trial,¹⁰ the prevalence of asthma was 10% among persons younger than 20 years old with type 1 diabetes and 16.1% among youth with type 2 diabetes, and differed according to race/ethnicity. Young persons with asthma were more likely to

have poorer glycemic control and higher *body mass index* (BMI) values, particularly in the group with type 1 diabetes. In the group with type 2 diabetes, more than 90% were overweight or obese, which may account for why BMI did not correlate with asthma in this group.

In terms of *chronic obstructive pulmonary disease* (COPD), the Offspring Cohort of the Framingham Heart Study¹¹ did not show an association between the diagnosis of diabetes and COPD, nor did diabetes seem to accelerate COPD in smokers. However, in patients hospitalized with COPD exacerbations, there is a high prevalence of comorbid diseases, including diabetes mellitus; of the patients hospitalized with COPD in a large multicenter study, 35.8% had diabetes.¹² In a large population-based cohort study¹³ of more than 350,000 patients with COPD or asthma, the use of inhaled corticosteroids was associated with an increased risk of requiring initial drug therapy for diabetes and an increased risk of requiring insulin in patients previously treated with oral antidiabetics over the 5-year observation period, with the caveat that diabetes mellitus prevalence increases with age. While a mainstay of treatment of asthma, inhaled corticosteroids are recommended in COPD patients for those who have more severe disease or who have frequent exacerbations¹⁴ and should not be prescribed unless warranted.

As for pulmonary function findings, a meta-analysis¹⁵ collectively representing the data from more than 3000 subjects with no prior pulmonary disease found that the presence of diabetes was associated with a mild to modest impairment in pulmonary function (Table 95-1). The pattern was restrictive with a mild decrease in diffusing capacity for carbon monoxide and was irrespective of BMI, smoking, diabetes duration, and HbA1c levels. In subanalyses, the association seemed to be more pronounced in type 2 diabetes than in type 1 diabetes. These mild functional abnormalities—generally well within 80% of the reference value¹⁶—have been ascribed to premature aging of the lungs in a fashion similar to nonenzymatic protein glycosylation and microangiopathic changes that develop in many affected organs in patients with diabetes.¹⁷ In summary, diabetes mellitus (in the absence of cystic fibrosis) may cause a mild decline in pulmonary function measurements, but does not appear to cause clinically significant pulmonary impairment, and routine pulmonary function testing in patients with diabetes is not warranted.

Compared with patients with cystic fibrosis alone, patients with cystic fibrosis-related diabetes had a higher rate of pulmonary infection with multiple antibiotic-resistant

Table 95-1 Pulmonary Complications of Diabetes Mellitus

Restrictive pattern on pulmonary function tests (mild)
Left ventricular dysfunction
Pleural effusions
Obstructive sleep apnea
Infections
Poor outcome from community-acquired pneumonia
Infections
<i>Legionella</i> pneumonia
Increased risk of aspiration pneumonia
Zygomycetes (mucormycosis)
Tuberculosis

*Pseudomonas aeruginosa*¹⁸ and a higher rate of treatment failure.¹⁹ Whether cystic fibrosis–related diabetes is associated with a higher rate of decline in pulmonary function compared with cystic fibrosis subjects without diabetes is unclear, because study outcomes have been mixed.^{20,21}

Cardiovascular and end-organ dysfunction develop in many patients with diabetes because of its chronic metabolic derangements. Cardiovascular factors appear to contribute more than pulmonary factors to impaired physical performance in patients with diabetes. In addition to the increased risk for cardiovascular events in patients with diabetes, there is an increased frequency of heart failure not explained by hypertension or coronary artery disease.²² Left ventricular systolic and diastolic dysfunction with exercise appears to be more common in patients with insulin-dependent diabetes than in those without diabetes.²³ In addition, when compared with patients with similar degrees of left ventricular dysfunction, exercise limitation and pleural effusions are more common in patients with diabetes.²⁴

Active cigarette smoking is a risk factor for the development of type 2 diabetes.²⁵ Smoking cessation has important health benefits in terms of risk reduction for a wide variety of complications, including cardiovascular events. However, weight gain is common with smoking cessation, typically 4 to 5 kg in the first year after cessation.^{26,27} In a large prospective multisite cohort study²⁸ of subjects who did not have diabetes at baseline, subjects who newly quit smoking had more significant increases in weight, waist circumference, and fasting glucose levels and a higher risk for development of type 2 diabetes than did persons who never smoked. These metabolic changes were more common in older men with heavy smoking habits before quitting; the increased risk for diabetes peaked within 3 years after quitting. Despite weight gain with smoking cessation, overall cardiovascular events decreased in patients who quit smoking.²⁹ In summary, both active smoking and the post-cessation period are associated with an increased risk for type 2 diabetes. Targeting the immediate post-quit period with more aggressive weight management and lifestyle changes in higher risk patients may be warranted.

Acute respiratory distress syndrome (ARDS) has been reported as a complication of diabetic ketoacidosis.³⁰ But diabetes mellitus—excluding diabetic ketoacidosis—is not associated with increased risk for development of ARDS compared to patients without diabetes, and it may even be

protective.^{31,32} Diabetes has been associated with a higher risk for development of idiopathic pulmonary fibrosis.^{33,34}

Newborn babies of diabetic mothers are at increased risk for macrosomia and preterm delivery^{35,36}; infants born to mothers with poor self-care are at greatest risk.³⁶ However, with good maternal metabolic control and accurate estimations of gestational age, most pregnant women with diabetes can deliver at or near term without associated respiratory distress syndrome.^{37,38}

Obesity is a risk factor for both type 2 diabetes mellitus and for obstructive sleep apnea. (See Chapter 88 for a full discussion of obstructive sleep apnea.) The prevalence of obstructive sleep apnea in patients with type 2 diabetes has been reported as 23% to 36%, and in patients with BMI greater than 35 kg/m², prevalence has been reported to be as high as 70%.^{39,40} Higher apnea-hypopnea indexes in diabetic patients with obstructive sleep apnea are associated with poorer glucose control.⁴¹ In addition, obstructive sleep apnea may impose a stress that increases sympathetic neural output during sleep, which in turn contributes to insulin resistance⁴²; moreover, oxygen desaturation is specifically associated with insulin resistance in severely obese patients.⁴³ In patients with diabetes, obstructive sleep apnea may increase the risk for diabetic peripheral neuropathy, perhaps due to increased oxidative stress and impaired microvascular regulation.⁴⁴ Continuous positive airway pressure therapy in diabetic patients with obstructive sleep apnea may not improve metabolic control unless there is also weight loss, at least in short-term follow-up.⁴⁵

Patients with diabetes are at increased risk for upper and lower airway infections, and are particularly predisposed to infection with Zygomycetes (mucormycosis), a group of infections caused by fungi in the *Mucor*, *Rhizopus*, and *Cunninghamella* genera. Angioinvasion is a hallmark of infections with mucormycosis. These ubiquitous saprophytic fungi are found in soil and decaying vegetation; infection is caused by inhalation of spores, hence the predilection for paranasal sinus and lung disease. Infection typically develops during or after an episode of diabetic ketoacidosis, perhaps because the fungi have an enzyme, ketone reductase, which favors growth in an acidic, hyperglycemic environment. Most patients have some underlying predisposition, of which diabetes mellitus is the most significant.⁴⁶ Five infectious manifestations have been described: rhinocerebral, pulmonary, disseminated, cutaneous, and gastrointestinal. Rhinocerebral infection is the most common form, especially in patients with diabetes. Presentation includes sudden periorbital or paranasal swelling and pain, bloody nasal discharge, and black necrotic nasal mucosa. Computed tomography (CT) findings are mostly nonspecific, but can include an air crescent sign (rim of air between necrotic lung and surrounding parenchyma) as well as the halo sign (rim of surrounding ground-glass opacities around dense consolidation).⁴⁷ Treatment requires control of the diabetes, antifungal therapy, and often aggressive surgical debridement. Mortality remains high, especially in patients with intracranial involvement.⁴⁸

Pulmonary mucormycosis mimics invasive aspergillosis and is found mostly in patients with diabetes, hematologic malignancy, or organ transplantation or in patients on glucocorticoid or deferoxamine therapy. Inhaled mold spores

Figure 95-1 Mucormycosis. Radiograph showing pulmonary infarction of the right lower lobe in a diabetic patient with pulmonary mucormycosis.

penetrate bronchiole walls, invade arterioles, and cause thrombosis and ischemia (Fig. 95-1). Nonspecific cough, fever, and pleuritic chest pain develop. Hemoptysis may develop in one fourth of cases and can be massive.⁴⁹ The most common chest radiographic pattern is consolidation; cavitation is seen in about one third of patients,⁵⁰ and adenopathy and pleural effusions may also be present but are less common. Patients with diabetes appear to have a predilection for endobronchial disease; however, sputum culture appears to have a very low yield for diagnosis. For specimens obtained at bronchoscopy, histopathologic examination appears to be more sensitive than fungal cultures. Treatment requires antifungal therapy (see Chapter 38) and, if localized, surgical resection. Bronchial stenosis is a potential sequela.

Diabetes mellitus is an independent risk factor for drug-sensitive⁵¹⁻⁵⁵ and multidrug-resistant tuberculosis.³⁸ A review of 13 observational studies revealed that diabetes mellitus was associated with an increased risk for tuberculosis (relative risk, 3.11; 95% CI 2.27-4.26),⁵³ an association that is supported by studies of diabetic children in South Africa and adults in Brazil.⁵⁵ Patients with tuberculosis and diabetes tended to be older, were more likely to yield positive smears for acid-fast bacilli, and had a higher mortality than patients with tuberculosis without diabetes.⁵⁵ The radiographic location of tuberculosis in diabetes (i.e., upper or lower lobe predilection) depends on the case series; patients with diabetes and tuberculosis appear to have a higher rate of cavitation.^{52,56} Treatment of latent tuberculosis in patients with diabetes with either a positive purified protein derivative skin test of greater than 10 mm of induration⁵⁷ or a positive interferon-gamma release assay is currently recommended.

Bacterial pneumonia may or may not be more frequent in patients with diabetes. In a study of more than 4000 elderly inhabitants in one township, diabetes mellitus was not an independent risk factor for community-acquired pneumonia.⁵⁸ Study findings are mixed as to whether diabetes portends a poorer outcome in persons in whom pneumonia develops.⁵⁹⁻⁶¹ Diabetes does not appear to be an independent risk factor for either health care-associated

pneumonia or ventilator-associated pneumonia.⁶² Given the demonstrated efficacy of pneumococcal vaccine and the increasing prevalence of penicillin resistance in pneumococcal strains, pneumococcal vaccination is recommended for virtually all people with diabetes. Diabetes appears to be a risk factor for *Legionella* pneumonia⁶³ and is associated with high mortality in infected persons.⁶⁴ Pharyngeal dysfunction and diabetic gastroparesis in persons with diabetes may predispose them to aspiration pneumonia.⁶⁵ Diabetes is a risk factor for chronic oral infections of caries and periodontitis, which also may contribute to the increased risk for aspiration pneumonia.⁶⁶ There is an increased incidence of bacterial pneumonia and associated mortality in patients with diabetes during seasonal influenza outbreaks.⁶⁷ Consistent with the recommendations of the Advisory Committee on Immunization Practices, influenza vaccination is recommended for patients with diabetes who are older than 6 months of age.⁶⁸ Regarding preventive practices in patients with known diabetes, approximately 60% have obtained annual influenza vaccines, whereas just 49% have met goals of pneumococcal vaccination.⁶⁹ As for other pathogens, preexisting diabetes has been associated with a higher mortality in patients with severe acute respiratory syndrome.⁷⁰

THYROID DISORDERS

The incidence of multinodular goiter is declining in the United States due to the routine use of iodized salt; nevertheless, neglected goiters are still detected. Because of the thyroid's ability to expand easily in the anterior space, bound only by skin, thin muscle, and connective tissue, even large goiters may not cause tracheal impingement. However, some goiters can cause dyspnea, stridor, wheezing, hoarseness, and cough via tracheal deviation—typically if there is unilateral or unequal lobe enlargement—and airway compression.⁷¹⁻⁷³ (Video 95-1). Compression or concentric narrowing of the trachea is more common if the goiter extends posteriorly to the trachea (Fig. 95-2). Although goiters typically grow slowly, occasionally patients present with acute respiratory distress requiring urgent intubation or semiurgent surgery.

Some goiters are substernal and/or intrathoracic. There is variability of the definition of “intrathoracic goiter”; most experts concur that some portion of the goiter is permanently retrosternal (below the sternal notch), even when the neck is retroflexed.⁷⁴ Bulky and/or substernal goiters may cause orthopnea because of airflow limitation in the supine position. In these patients, flow-volume loops in the recumbent position may demonstrate upper airway obstruction not apparent in upright testing.⁷³ CT scanning and magnetic resonance imaging generally are the most useful diagnostic imaging studies and can estimate the degree of tracheal compression.⁷⁵

Of particular note, CT scanning with iodinated contrast media should generally be avoided because it precludes thyroid nuclear imaging for several weeks and can trigger hyperthyroidism. Surgical resection of substernal goiters is recommended and usually relieves compressive symptoms.^{71,76} Postoperative tracheomalacia appears to be rare.⁷¹

Figure 95-2 Thyroid goiter. Magnetic resonance images show a massive goiter in a 55-year-old man who presented with a change in his voice and increased shortness of breath. Endotracheal intubation required flexible bronchoscopy, followed by uneventful resection of a 900-g multinodular goiter. Coronal (A) and axial (B) gadolinium-enhanced images of the neck reveal tracheal deviation and compression.

Figure 95-3 Metastatic thyroid cancer. Computed tomography scan of a patient showing metastatic thyroid cancer with micrometastases. (Courtesy Michael B. Gotway, MD.)

Iodine-131 is an alternative therapy for some patients with large goiters including those with intrathoracic extension who are not surgical candidates because of comorbid illnesses.^{77,78} For patients with baseline tracheal compression, there is often some temporary goiter enlargement from edema and additional airway compromise in the week following ¹³¹I treatment. Even so, with glucocorticoid prophylaxis, most patients do well and have subsequent goiter shrinkage.⁷⁹ Alternatively, bronchoscopic insertion of tracheal stents can relieve large airway obstruction from compressive benign or malignant nonoperable thyroid disease.⁸⁰ Large, multinodular goiters with retrolaryngopharyngeal extension can also cause obstructive sleep apnea, which can resolve after total thyroidectomy.^{81,82}

Thyroid carcinoma accounts for 1% of all new malignancies; the most common is papillary thyroid carcinoma. Of these, 10% to 15% will develop metastases, the vast majority of which are within the thoracic cavity. A miliary pattern of metastases can be seen, as well as larger nodules, and even localized pulmonary opacities⁸³ (Fig. 95-3 and Video 95-2). Depending on the lung burden of cancer, dyspnea may be present. Thyroid cancer can also directly invade the

trachea. In patients who are otherwise good surgical candidates, resection with tracheal reconstruction has been successful.⁸⁴

Smoking is a risk factor for hyperthyroidism, including Graves disease, toxic nodular goiter, and autoimmune hypothyroidism (Hashimoto thyroiditis), especially in women.⁸⁵⁻⁸⁷ Smoking increases the risk of Graves ophthalmopathy beyond the risk associated with hyperthyroidism alone.

HYPERTHYROIDISM

Many patients with hyperthyroidism complain of both resting and exertional dyspnea. Congestive heart failure likely explains some of these complaints⁸⁸ and is the presenting feature in 6% of patients with newly diagnosed hyperthyroidism.⁸⁹ Some hyperthyroid patients have decreased vital capacity,⁹⁰ decreased respiratory muscle strength,⁸⁹⁻⁹³ and elevated resting minute ventilation (perhaps due to increased central ventilatory drive) that becomes excessive with exercise.⁹² With treatment, vital capacity and respiratory muscle strength improve,⁹⁰ although some patients have persistent dyspnea.⁹¹

Patients with coincident asthma and thyrotoxicosis may have worsening asthma control if β -blocker agents are used to control manifestations of hyperthyroidism. There may be an association between atopic disease, asthma, and Graves disease.⁹⁴ Approximately 30% of patients with hyperthyroid Graves disease have an elevation in serum *immunoglobulin E* (IgE) levels, and those with elevated serum IgE are more likely to have a personal or family history of atopy.⁹⁵

Several reports have suggested a link between hyperthyroidism, especially Graves disease, and pulmonary hypertension in which the pulmonary artery pressures can improve and even normalize with treatment of the hyperthyroidism.⁹⁶⁻⁹⁸ The explanation for this association is not clear, but may be due to a generalized autoimmune state, a direct influence of thyroid hormone on pulmonary vasculature, changes in metabolism of pulmonary vasculature vasodilators/vasoconstrictors, decreased surfactant production and function, or excess cardiovascular

stimulation by the sympathoadrenal system. Treatment of the hyperthyroidism is important to relieve the additional burden of cardiovascular stress on the pulmonary vascular system.⁹⁷ Rarely, mothers with hyperthyroidism from Graves disease deliver infants with hyperthyroidism via placental passage of maternal thyrotropin receptor-stimulating antibodies. In addition to a variety of infant metabolic and developmental problems, neonatal Graves disease has been associated with persistent pulmonary hypertension in newborns.⁹⁹ Interestingly, there may also be an increased prevalence of hypothyroidism in patients with primary pulmonary hypertension.¹⁰⁰

Furthermore, several reports of an increased presence of antinuclear cytoplasmic antibodies and even granulomatosis with polyangiitis (Wegener granulomatosis) have been documented in patients with Graves disease treated with propylthiouracil.¹⁰¹ Propylthiouracil-induced nonspecific interstitial pneumonia¹⁰² and alveolar hemorrhage¹⁰³ have also been reported.

HYPOTHYROIDISM

Hypothyroidism has been associated with dyspnea on exertion, alveolar hypoventilation, respiratory failure, obstructive and central sleep apnea, and pleural effusions. Lung volumes are generally normal or mildly decreased in mixed populations of obese and nonobese hypothyroid patients.^{104,105} Lung volumes typically, although not uniformly, improve with thyroid replacement and/or weight loss. A reduced diffusing capacity for carbon monoxide can be seen in some hypothyroid, nonobese patients with normal lung volumes and arterial blood gases that improve to near-normal after replacement therapy.¹⁰⁵ Hypothyroidism is associated with overall respiratory muscle weakness as measured by maximal inspiratory and expiratory pressures, and the degree of impairment is linearly related to the degree of pretreatment hypothyroidism.¹⁰⁶ Diaphragmatic muscle weakness in both obese and nonobese hypothyroid patients may range from mild impairment, which limits exercise tolerance, to severe dysfunction, with marked resting dyspnea and chronic hypercarbia.¹⁰⁴ Thyroid replacement therapy can improve respiratory muscle strength. Some nonobese and obese hypothyroid patients have a markedly blunted ventilatory response to hypoxia and hypercapnia,^{105,107} which improves often within weeks of initiation of thyroid hormone replacement. This improvement is not associated with changes in spirometric function or maximal voluntary ventilation, thus suggesting a central cause for the abnormal ventilatory response. Hypothyroidism can cause respiratory failure that may require prolonged mechanical ventilation.¹⁰⁷

Although up to 25% of patients with hypothyroidism have radiographic evidence of a pleural effusion, most patients also have underlying congestive heart failure (Table 95-2).¹⁰⁸ A small percentage of hypothyroid patients do not have another disease process that would explain the effusion. In these patients, the hypothyroid-related effusions tend to be small, less than one third of the pleural space; unilateral or bilateral; serous or serosanguineous; and transudates or exudates, although generally noninflammatory.¹⁰⁸ Hypothyroid-related effusions typically resolve with treatment of the hypothyroidism.¹⁰⁸

Table 95-2 Etiologies of Pleural Effusions in Hypothyroid Patients (n = 28)

Etiology	No.
Nonhypothyroid-associated pleural effusions	22
Pneumonia	7
Congestive heart failure	7
Malignancy	4
Atelectasis	2
Pancreatitis	1
Cirrhosis with ascites	1
Hypothyroid pleural effusion	5
Hypothyroid-associated effusion due to pericardial involvement	1

Modified from Gottehrer A, Roa J, Stanford GG, et al: Hypothyroidism and pleural effusions. *Chest* 98:1130–1132, 1990.

Hypothyroidism can predispose patients to sleep apnea,^{109,110} possibly from narrowing of the upper airway from mucopolysaccharide and protein deposition in the tongue and oropharynx,¹¹¹ from abnormalities in ventilatory control, and/or from weight gain. Hypothyroidism can contribute to the neurocognitive impairment found in patients with sleep apnea.¹¹² In one case series, only 3.1% of patients with obstructive sleep apnea were found to have hypothyroidism¹¹⁰; in contrast, 25% of newly diagnosed hypothyroid patients were found to have obstructive sleep apnea. Age and body weight were the best predictors of associated obstructive sleep apnea.¹¹⁰ Hypothyroid patients with obstructive sleep apnea have blunted ventilatory responses to both hypoxia and hypercapnia. Some studies have shown improvement in sleep respiratory disturbance index and awake ventilatory response to hypoxia and hypercapnia with thyroid replacement^{110,113}; in other studies, however, investigators found less than full improvement or no improvement in sleep apnea with thyroid replacement.^{114,115} Central sleep apnea can also be detected in hypothyroid patients, and the blunted ventilatory response to hypoxia may improve with thyroid replacement.¹¹⁴

Thyroid hormones play an important role in the growth and development of the lung and in the maturation of the lung's surfactant system.^{116,117} Transient hypothyroxinemia is common in premature infants, as is respiratory distress syndrome. However, the administration of maternal antenatal thyrotropin-releasing hormone, which increases fetal thyroid hormone levels, did not decrease the frequency or severity of respiratory distress syndrome in premature babies in a large multicenter trial.¹¹⁸ Treatment of premature infants with thyroxine also did not decrease the incidence of respiratory distress syndrome, the use of surfactant therapy, or the overall developmental outcome at 24 months.¹¹⁹

The “brain-thyroid-lung syndrome”^{120–122} is a rare form of neonatal progressive respiratory failure characterized by chorea or cerebral dysgenesis, congenital hypothyroidism, and respiratory disease. It is related to defects of the *NKX2-1* gene encoding thyroid transcription factor-1, which appears to be critical for central nervous system, thyroid, and lung development and function. In the lung, thyroid transcription factor-1 deficiency syndrome leads to a disturbance of surfactant protein-A production, resulting in

Figure 95-4 Metastatic calcification. Frontal chest radiograph (A) and corresponding axial chest CT scan (B) show the apical predilection of metastatic pulmonary calcification that can be seen in hyperparathyroidism.

spectrum of disease from mild to progressive and fatal respiratory failure.

PARATHYROID DISEASES

Hyperparathyroidism, typically secondary hyperparathyroidism in patients with end-stage renal disease, can cause diffuse metastatic calcification in the lungs. Metastatic calcification is the deposition of calcium salts in previously normal tissue; in contrast, dystrophic calcification is the calcification of diseased or abnormal tissue, as in granulomatous processes. Despite dietary phosphate restriction, administration of phosphate binders, and hemodialysis, patients with renal failure are at risk for metastatic calcification, especially when the calcium-phosphorus concentration product increases above $70 \text{ mg}^2/\text{dL}^2$. Calcium salts tend to precipitate in alkaline conditions. Indeed, metastatic calcification has a predilection for the apical portions of the lungs (Fig. 95-4), the stomach, and the kidneys—all tissues with relative alkalinity, because of either carbon dioxide removal or hydrogen ion excretion. Due to the higher ventilation-perfusion ratio and lower carbon dioxide concentration at the lung apex, it is estimated that the pH at the apex is 7.5 compared to a pH of 7.3 at the base.^{123,124} Other common sites of deposition include soft tissues and the skin. Pulmonary metastatic calcific nodules may deposit predominantly in the alveolar septa and are associated with varying degrees of fibrosis and septal thickening. This phenomenon appears to be common; from 60% to 80% of dialysis patients on long-term therapy have autopsy or scintigraphic evidence of pulmonary metastatic calcification.¹²⁵

Most patients with end-stage renal disease and metastatic pulmonary calcification are asymptomatic and have normal chest radiographs and pulmonary function. However, patients with heavy deposition of calcific nodules may complain of dyspnea and nonproductive cough, and can rarely progress to respiratory failure.¹²⁶ Radiographically, patients with more extensive calcification typically have numerous nodules about 3 to 10 mm in size that are better visualized on CT scans than on plain chest radiographs (Fig. 95-5).¹²⁷

Figure 95-5 Metastatic calcification in the lungs secondary to chronic renal failure. A 59-year-old man with end-stage renal disease for 5 years complained of chronic progressive shortness of breath. The serum calcium level was 9.9 mg/dL (normal range, 8.5 to 10.5 mg/dL) and the parathyroid hormone level was 271 pg/mL (normal for the laboratory, 11 to 54 pg/mL). High-resolution computed tomography revealed numerous nodular ground-glass densities in a peribronchial pattern, most prominently in the upper lobes. (Courtesy Marcia McCowin, MD.)

In addition to the nodular densities, patchy consolidation and ground-glass attenuation may be seen. The calcific nature of the nodules may not be apparent on plain radiographic or even CT images, perhaps due to the small size of the calcium deposits. However, radionuclide bone scans usually reveal intense uptake in the lungs and other affected organs (Fig. 95-6).¹²⁵ Pulmonary function tests in patients with extensive metastatic calcification may show ventilatory restriction with hypoxemia and low diffusing capacity for carbon monoxide.¹²³ Parathyroidectomy or treatment with vitamin D analogues can decrease the calcium-phosphorus double product, reverse bone scan abnormalities and organ deposition, and presumably improve pulmonary function.

Hyperparathyroidism is also associated with calcification in pulmonary arterial and bronchial walls. Of note, about one third of patients with end-stage renal disease on long-term hemodialysis via arteriovenous access have pulmonary hypertension,^{128,129} but pulmonary hypertension does not seem to correlate with the presence or severity of pulmonary artery calcification or parathyroid hormone levels.^{128,130}

Figure 95-6 Metastatic calcification in the lungs caused by chronic renal failure. This is the same patient as in Figure 95-5. Whole-body bone imaging with technetium-99m-diphosphonate revealed diffuse soft tissue avidity in both lungs.

Rarely, enlarged mediastinal parathyroid cysts can cause tracheal compression with stridor or vocal cord impingement and hoarseness, or both. Surgical excision is the treatment of choice.¹³¹

Hyperparathyroidism is frequently associated with muscle weakness and fatigue. Respiratory muscle function can be affected as well, and post-parathyroidectomy improvement in forced vital capacity and forced expiratory volume in 1 second values correlates with preoperative serum calcium and preoperative parathyroid hormone values.¹³²

Vitamin D deficiency and metabolic bone disease from a variety of causes can affect skeletal muscle strength and bone integrity and, in turn, may impair pulmonary function. Unrelated to skeletal effects, vitamin D deficiency has been associated with increased severity of asthma¹³³ and increased risk for asthma exacerbations in children.^{134,135} Vitamin D deficiency has been associated with impaired pulmonary function in adults^{136,137} and a more rapid decline in pulmonary function in smokers.¹³⁸ Vitamin D deficiency has not been associated with COPD exacerbations,¹³⁹ and supplementation with high-dose vitamin D does not reduce future COPD exacerbations.¹⁴⁰ Hypophosphatasia from mutations in the gene for the tissue-nonspecific isozyme of alkaline phosphatase can lead to rickets or osteomalacia. Fatal respiratory insufficiency due to progressive chest deformity can develop in severely affected babies. Enzyme replacement therapy is associated with improved findings

on skeletal radiographs and improved pulmonary and physical function in affected children.¹⁴¹

ADRENAL DISEASES

Endogenous Cushing syndrome (i.e., not from glucocorticoid administration) may be caused by pituitary Cushing disease, adrenal neoplasia, or ectopic adrenocorticotrophic hormone production from small-cell lung cancer or from carcinoids arising from a variety of organs, especially the lung, including the variation of pulmonary carcinoid tumorlets.¹⁴²⁻¹⁴⁴ Cortisol levels tend to be much higher with ectopic adrenocorticotrophic hormone production and adrenal neoplasia than with pituitary Cushing disease and pose a greater risk for infection. Hypercortisolism particularly predisposes patients to mucocutaneous fungal infections and opportunistic pulmonary infections. The most common pulmonary infections are caused by *Cryptococcus*, *Aspergillus*, *Nocardia*, *Pneumocystis*, and *Mycobacterium tuberculosis*.¹⁴⁵⁻¹⁴⁸ *Pneumocystis jirovecii* pneumonia tends to develop in patients with especially high morning cortisol levels.¹⁰³ Correction of hypercortisolism is an important adjunct to antimicrobial therapy. Cushing syndrome is also associated with a hypercoagulable state and an increase in clinically significant thromboembolic events.^{149,150} Even in patients without baseline hypercortisolism, cortisol levels increase in stress and extremely elevated cortisol levels at presentation appear to be independent predictors of worse outcomes in community-acquired pneumonia.^{151,152}

Adrenal insufficiency may be due to either primary adrenal failure (Addison disease) or secondary adrenal insufficiency. Secondary adrenal insufficiency is most commonly iatrogenic as a result of the withdrawal of exogenous glucocorticoid therapy, or results directly from disease of the hypothalamic-pituitary axis. In industrialized countries, 70% to 80% of cases of Addison disease are autoimmune in origin; in contrast, in resource-poor countries, tuberculosis remains the most common cause.^{153,154} CT scanning is sometimes helpful in determining the cause of Addison disease, because tuberculosis and histoplasmosis may cause adrenal calcification.¹⁵⁵ Adrenal insufficiency via hypothalamic-pituitary axis dysfunction may be seen in stressed, very-low-birth-weight infants and may render them more susceptible to bronchopulmonary dysplasia.¹⁵⁶

ACROMEGALY

Acromegaly is a disorder of excess growth hormone secretion in adults, most commonly from a benign pituitary adenoma. Rarely, bronchial carcinoid or small-cell lung cancer can produce excess growth hormone-releasing factor, which stimulates excess growth hormone secretion. Clinically, acromegaly is characterized by excessive bone growth, soft tissue hypertrophy, and coarsening of facial features. These changes appear to be due to high levels of growth hormone and *insulin-like growth factor I* (IGF-I), which is secreted in response to growth hormone; the net effect is an increase in somatic growth and metabolic disturbances. Mortality in acromegaly is increased primarily

from cardiovascular disease,¹⁵⁷ although control of acromegaly can lead to a significant decrease in coronary heart disease risk factors, especially in patients whose IGF-I levels are normalized.¹⁵⁸

Patients with acromegaly can develop macroglossia, nasal polyps, oropharyngeal airway narrowing, and vocal cord restriction and edema. In addition, coincidental goiter is not uncommon and can contribute to upper airway narrowing.^{157,159} Respiratory manifestations of acromegaly include sleep apnea, extrathoracic airway obstruction, vocal cord dysfunction, and difficult intubation.^{157,159} The prevalence of sleep apnea has been reported as between 20% and 60%.¹⁶⁰⁻¹⁶² Increased rates of obstructive sleep apnea may be due to a narrowed upper airway from osseous enlargement, hypertrophy of tissues in the oropharynx, inspiratory collapse of the hypopharynx, and macroglossia. The circumference of the neck and fingers, but not BMI, are predictive of the development of sleep apnea in acromegaly.¹⁶² Obstructive sleep apnea may improve with treatment of acromegaly with pituitary ablation¹⁶³ or somatostatin analogues, but is highly variable.^{160,161,164,165} Persistence of obstructive sleep apnea after treatment may be due to irreversible upper airway remodeling. Central sleep apnea is also common. Patients with central sleep apnea and acromegaly have higher growth hormone and IGF-I levels and higher ventilatory responses to carbon dioxide than acromegalic patients with obstructive sleep apnea.¹⁶⁶ Central sleep apnea in these patients may therefore be due to altered ventilatory control.

Total lung capacity and vital capacity are typically increased in patients with acromegaly compared with controls,¹⁶⁷⁻¹⁷² and appear to correlate with both the duration of acromegaly and in level of IGF-I.^{169,173} Possible causes for the increased lung volumes in these patients include hypertrophy or enlargement of individual alveoli, or an increase in the number of alveoli.^{167,170,171} Diffusing capacity for carbon monoxide may be within normal limits^{167,170} or elevated.¹⁶⁸ Changes in vertebrae and rib morphology contribute to the barrel chest of patients with acromegaly. In addition, with acromegaly, there is a decrease in respiratory muscle force that may contribute to increased dyspnea and fatigue with exercise.¹⁷²

Evidence of a variable extrathoracic airway obstruction on flow-volume loops is seen in 30% to 50% of patients with acromegaly.¹⁶⁹ As noted, intubation may be more difficult in patients with acromegaly because of vocal cord fixation, vocal cord edema, prolapse of an enlarged tongue, and soft tissue thickening of the oropharynx.¹⁷⁴ Preoperative treatment of patients with somatostatin analogues may decrease soft tissue swelling and enable easier intubation.¹⁶⁵

Key Points

- Diabetes mellitus, by far the most common endocrine disorder, is associated with sleep apnea and predisposes to certain bacterial, fungal, and mycobacterial respiratory infections. Cigarette smoking is a risk factor for type 2 diabetes. Patients with diabetes should receive pneumococcal and influenza vaccinations and, because of an increased risk for progression to active tuberculosis, should receive treatment for latent tuberculosis infection if they have a tuberculin skin test greater than 10 mm or a positive interferon-gamma release assay.
- Thyroid enlargement may cause upper airway compression. Patients with hyperthyroidism may have dyspnea worsened by decreases in vital capacity and respiratory muscle strength. More commonly, patients with hypothyroidism suffer from dyspnea, alveolar hypoventilation, pleural effusion, and, sometimes, respiratory failure.
- Secondary hyperparathyroidism from end-stage renal disease often causes diffuse metastatic pulmonary calcification, which frequently is asymptomatic.
- Endogenous Cushing syndrome predisposes to a variety of opportunistic infections, whereas acromegaly from excess growth hormone is associated with a high prevalence of sleep apnea, and may lead to upper airway structural disorders.

INTRODUCTION

Both respiratory physiology and the respiratory tract's susceptibility to disease are uniquely altered in gynecologic and obstetric conditions, including normal pregnancy. This chapter summarizes normal physiologic alterations during pregnancy and considers pathologic diseases and disorders that arise during pregnancy. Airway disorders, infectious diseases, pulmonary vascular and embolic disorders, and acute lung injury are discussed. Finally, pleural and parenchymal diseases that arise as a consequence of gynecologic conditions are addressed.

PHYSIOLOGIC ALTERATIONS DURING NORMAL PREGNANCY

Profound alterations of respiratory function and cardiovascular physiology accompany normal pregnancy in healthy women; these conditions contribute to many of the disorders of the lungs during pregnancy. The adaptive changes during the gravid period are designed to support maternal and fetal well-being during the special stresses of fetal growth and parturition, but they may exacerbate some underlying disorders and confuse interpretation of laboratory and imaging studies used to assess many other common conditions.

ALTERATIONS IN RESPIRATORY PHYSIOLOGY

Upper airway, particularly nasal, mucosal edema is common in normal pregnancy. About 20% of gravid women complain of rhinitis symptoms, now attributed at least partially to placental growth hormone's effects on mucosal congestion.¹ The symptoms begin in the first trimester and persist throughout gestation. Many patients thought to have rhinitis of pregnancy may actually have other or coincident causes of rhinitis.² An important implication of nasal mucosal edema in pregnancy is that it predisposes to nosebleeds, including from nasal intubations, so an oral approach is favored if intubation is required at the time of delivery.

Chest wall configuration is also altered, partially due to a 50% increase in the average costal angle³ and partially due to an increase in the circumference of the lower chest wall. Diaphragmatic position is elevated 4 to 5 cm, but excursion does not diminish.³ Muscle strength, as measured by maximum transdiaphragmatic pressure, does not appear to be diminished from its usual mean value of about 95 cm H₂O,⁴ allowing reserve for both the augmented minute ventilation of normal pregnancy and the stresses of delivery.

Important changes take place in lung function and lung volumes. The loss of lung volume resulting from elevation of the diaphragm is only partially offset by the increase in chest wall diameter, and therefore *functional residual capacity* (FRC) is diminished by about 18%, or 300 to 500 mL.⁵ This reduction in FRC comprises an equal reduction in both the expiratory reserve volume and the residual volume.^{3,5} The loss of FRC at term is made worse by recumbency, when diaphragm elevation is greatest because of the higher intra-abdominal pressure. Increased pulmonary blood volume in pregnancy may also serve to lower the FRC.⁶ This reduction in FRC is associated clinically with increased uptake and elimination of inhalational anesthetics and with rapid desaturation during hypopnea, as a result of the loss of the oxygen reservoir function of end-expiratory lung volume.⁷ Endotracheal intubation at term is thus substantially more hazardous than in nonpregnant patients.

Airway function is largely unchanged during pregnancy.³ Airway resistance may actually decrease slightly. Routine measurements of air flow, such as the FEV₁ and flow rates at midexpiratory lung volume (forced expiratory flow between 25% and 75% of FVC, or FEF_{25%-75%}) are thus valuable in assessing dyspnea during pregnancy.

The most striking changes are in respiratory drive and minute ventilation. Central drive, as assessed by the inspiratory pressure measured 100 msec after airway occlusion at the onset of inspiration (P_{0.1}), is increased by 13 weeks and continues to increase to week 37 of gestation, returning to normal by 24 weeks after delivery.⁴ These serial changes in respiratory drive appear to correlate with changes in serum progesterone levels.^{4,8} Carbon dioxide production itself increases one third to one half by the last trimester, but this is more than made up for by the greatly augmented ventilation, so primary respiratory alkalosis with renal

Figure 96-1 The physiology of pregnancy. The expected values for minute ventilation, the ventilatory equivalent for oxygen, oxygen uptake, and basal metabolism are shown at monthly intervals throughout pregnancy. (From Prowse CM, Gaensler EA: Respiratory and acid-base changes during pregnancy. *Anesthesiology* 26:381, 1965.)

bicarbonate wasting as compensation is a normal finding.⁹ Arterial blood gas measurements typically show the pH ranging from 7.40 to 7.47, with PCO_2 reaching as low as 28 to 32 mm Hg. PO_2 rises slightly as a result of the increase in alveolar ventilation.

Most of the increase in minute ventilation is due to a 30% to 35% increase in tidal volume. Respiratory rate is unchanged early and rises only about 10% later in pregnancy. Oxygen consumption increases 20% to 33% in pregnancy, owing to both maternal and fetal metabolic demands. Changes in some of these parameters are shown in Figure 96-1.

ALTERATIONS IN CARDIOVASCULAR PHYSIOLOGY

Adaptive cardiovascular changes are designed to support both maternal and fetal circulations but contribute to the risk for hydrostatic pulmonary edema; accordingly, cardiac disorders during pregnancy often present as respiratory failure. During normal pregnancy, maternal blood volume increases by about 2 L, or 40%.^{10,11} Red blood cell mass increases as well, but only by 20% to 30%, accounting for the normal 10% to 12% decrease in hematocrit.^{11,12} Plasma oncotic pressure also drops as intravascular volume expands, increasing the risk for pulmonary edema at lower intravascular hydrostatic pressures. During the 24 hours after parturition, oncotic pressure falls further because of blood loss and mobilization of extravascular fluid.

The enlarged intravascular volume of pregnancy is accommodated chiefly by venous capacitance vessels. Central venous pressure and pulmonary capillary occlusion (“wedge”) pressure are unchanged, reflecting an increase in left ventricular compliance, as evidenced by the enlarged cardiac silhouette seen on chest radiograph. The increased left ventricular end-diastolic volume results in an augmented stroke volume (ejection fraction is little changed), but *systemic vascular resistance* (SVR) diminishes.^{12,13} These changes account for the 30% to 45% increase in cardiac

Figure 96-2 Changes in physiology in the supine position. Because the gravid uterus compromises venous return, there are characteristic changes in maternal heart rate, stroke volume, and cardiac output during pregnancy with the pregnant subject in the supine compared to the lateral position. (From Yanagihara N, von Leden H, Werner-Kukuk E: The physical parameters of cough: the larynx in a normal single cough. *Acta Otolaryngologica* (Stockholm) 61:495–510, 1966.)

output reached by 25 to 32 weeks of gestation. After 5 weeks, heart rate increases as well,¹⁴ but less so than stroke volume. Some of these changes, as well as the effects of supine versus lateral positioning, are depicted in Figure 96-2.

OBSTETRIC DISORDERS AND THE LUNGS

Gravid and newly postpartum patients may develop pregnancy-specific disorders but also continue to experience common disorders that arise outside of pregnancy; the natural history or frequency of coexisting disorders is sometimes altered by the gravid state. Even for diseases not altered by pregnancy, management requires special knowledge of the safety of therapies. Specific diseases are considered here with these principles in mind.

OBSTRUCTIVE AIRWAY DISEASE

Asthma

Asthma affects 4% to 8% of the general population and is the most common pulmonary disorder in pregnancy. The *Working Group on Asthma and Pregnancy of the National Asthma Education and Prevention Program* (NAEPP) estimated that 3.7% to 8.4% of pregnancies are complicated by asthma.¹⁵ Maternal asthma increases the risk of preeclampsia, preterm birth, infants with low birth weight, intrauterine growth restriction or congenital malformations, and perinatal death.¹⁶

Studies examining the hormonal milieu have suggested that progesterone might diminish smooth muscle contractility in the lung, as it does in the uterus and gut. Juniper

and colleagues¹⁷ performed serial measurements of bronchial reactivity to methacholine challenge in 16 women before and during pregnancy and found a decrease in airway hyperresponsiveness. Clinical and epidemiologic studies, however, have failed to provide convincing evidence of any consistent change in the natural history of asthma during pregnancy. Turner and coworkers,¹⁸ for example, compiled the results of nine studies of asthma symptoms reported by pregnant women. Among them, 22% reported worsening, 29% reported improvement, and 49% reported no change. Other studies have reported similar figures, with about 23% to 42% worsening, 18% to 36% improving, and 40% exhibiting no change.^{19,20} The differences reported in the natural history probably reflect differences in study populations, smoking history, ethnicity, or other variables.²¹

Fetal and maternal outcome for asthma and pregnancy have also been examined in a variety of studies since 1980. Adverse outcomes, including an increased incidence of preterm labor, low neonatal birth weight, increased perinatal mortality, preeclampsia, vaginal hemorrhage, chronic hypertension, and complicated labor, have been reported.^{15,21} A large epidemiologic study from Sweden did confirm an association of asthma with perinatal mortality and low birth weight.²² Nonetheless, adequate therapy tailored to disease severity is associated with good outcomes.²³ Therapy of asthma in pregnancy should be individualized according to severity of disease and frequency of symptoms, as outlined by the NAEPP.¹⁵ Objective measurement of lung volumes and flow should be part of the regimen. Initial office spirometry is recommended, and home peak flow monitoring should be considered. For women who have asthma attacks during labor, fetal monitoring is considered essential by the NAEPP.

Therapy should be based on a step approach.¹⁵ Mild intermittent asthma is best managed with inhaled short-acting β_2 -agonists, for symptomatic relief. Asthma that causes more than occasional symptoms should be treated daily with anti-inflammatory therapy, with the preferred choice being inhaled corticosteroids. Budesonide is the best studied and hence preferred, although substantive safety data exist for beclomethasone as well. Alternative therapies include cromolyn, sustained-release theophylline, or a leukotriene antagonist.¹⁵ Frequent need for short-acting β_2 -agonists should prompt institution of, or an increase in, the use of anti-inflammatory agents to treat, rather than to mask, a deteriorating clinical course. Long-acting β -agonists should only be used concurrently with long-acting inhaled corticosteroids.²¹ Finally, the addition of rapidly tapered courses of oral corticosteroids should be considered for those with acute severe asthma or patients with active symptoms who are already using inhaled steroids and β -agonists. Daily or alternate-day oral steroid administration (e.g., prednisone 40 mg/day) is sometimes required.¹⁵ Extensive practice algorithms have been made available by the NAEPP Working Group on Asthma and Pregnancy.¹⁵

A large body of literature has examined the topic of possible teratogenicity of agents used in the pharmacotherapy of asthma in pregnancy. In general, the risks of poorly controlled asthma far outweigh the possible hazards of drug therapy. Both animal and human studies of β_2 -agonists, administered either by inhalation or systemically, have

indicated an acceptable safety profile for the fetus. They are also safe for use during lactation. Nonselective β -agonists, such as epinephrine, carry a risk of uterine vasoconstriction in animal models²⁵ and are probably best avoided. Acceptable β_2 -agonists in pregnancy include metaproterenol, albuterol, pirbuterol, bitolterol, and terbutaline. Because the toxicology and pharmacology of the long-acting β -agonists salmeterol and formoterol are expected to be similar to shorter-acting β_2 -agonists, these drugs have been recommended in patients with poor control on a combination of inhaled long-acting corticosteroids and short-acting β -agonists.^{23,24} Limited data suggest that these drugs are safe in pregnancy.²⁶

Theophylline also has a long history of use during pregnancy and is considered safe, but the therapeutic range in plasma should be lowered to 5 to 12 $\mu\text{g/mL}$ because of diminished protein binding during pregnancy. Theophylline passes freely to the fetus, and newborns occasionally show signs of theophylline toxicity, particularly when maternal blood levels are high. Theophylline is also transmitted to breast milk, with a milk-to-serum ratio of about 0.70; but, in general, less than 1% of the maternal dose is transferred to the infant. Animal studies suggest that the leukotriene inhibitors montelukast and zafirlukast are safe in pregnancy, and they can be continued in patients who have previously responded.^{25,27,28} Zileuton should be avoided because animal studies have raised questions about its safety in pregnancy.

Animal studies have shown an increased incidence of cleft palate with use of corticosteroids, and limited human data support this association, with an estimated excess risk of 0.2% to 0.3% when used in the first trimester.¹⁵ Systemic corticosteroids have also been reported to cause intrauterine growth restriction, but of a relatively modest degree. Halogenated corticosteroids do not cross the placenta easily, and so fetal and neonatal adrenal suppression is not a major concern with these compounds.¹⁵ Overall, risk-benefit considerations nonetheless favor their use in persistent severe asthma with exacerbations unresponsive to other measures. One study suggests that higher doses of inhaled corticosteroids (i.e., beclomethasone > 1000 mcg/day) may be associated with a small increased risk of congenital abnormalities, although the confounding effect of increased asthma severity cannot be excluded.²⁹ There are limited data to confirm the safety of newer inhaled corticosteroids.²⁶ Table 96-1 summarizes the U.S. Food and Drug Administration (FDA) safety classification for agents useful for the treatment of asthma in pregnancy.

Labor and delivery can be especially hazardous for asthmatic patients, partly because of the drugs commonly administered. Narcotics other than fentanyl release histamine, which may worsen bronchospasm. Lumbar epidural analgesia is generally preferred, but if general anesthesia is to be used, pretreatment with atropine or glycopyrrolate assists bronchodilation. Ketamine is the preferred anesthetic, although halogenated anesthetics at low concentrations may provide bronchodilation as well.¹⁵ Preterm labor may be safely treated with nifedipine or magnesium sulfate. Oxytocin is the optimal labor induction agent and is useful for postpartum hemorrhage, but 15-methyl prostaglandin F_{2a} , methylergonovine, and ergonovine may cause bronchospasm and should be avoided if possible.

Table 96-1 Potential Fetal Risk of Drug Therapy in Pregnancy According to the FDA Classification for Safety in Pregnancy*

Drug	FDA Classification [†]
ASTHMA THERAPY	
Inhaled Bronchodilators	
Albuterol (salbutamol)	C
Terbutaline	C
Ipratropium	B
Salmeterol	C
Formoterol	C
Inhaled Corticosteroids	
Beclomethasone	C
Budesonide	B
Fluticasone	C
Leukotriene Antagonists	
Zafirlukast	B
Montelukast	B
Zileuton	C
Other Agents for Asthma	
Theophylline	C
Cromolyn	B
Systemic corticosteroids	B
ANTICOAGULANTS	
Heparin	C
Low-molecular-weight heparin	B
Warfarin	X
ANTIBIOTICS	
Penicillins	B
Cephalosporins	B
Macrolides	B/C
Quinolones	C
Clindamycin	B
Tetracyclines	D

*Although the U.S. Food and Drug Administration (FDA) classification provides an overview of fetal risk, it is being replaced by a narrative description of known drug effects. Detailed information should therefore be consulted for individual drugs. Classification of individual drugs may change as the literature evolves.

[†]Class B: Animal studies do not indicate a risk to the fetus, and there are no controlled human studies; or animal studies do show an adverse effect on the fetus, but well-controlled studies in pregnant women have failed to demonstrate a risk to the fetus. Class C: Studies in animals have shown the drug to have teratogenic or embryocidal effects, but there are no controlled studies in women; or no studies are available in either animals or women. Class D: Positive evidence of human fetal risk exists, but benefits in certain situations (e.g., life-threatening situations or diseases for which safer drugs cannot be used or are ineffective) may make use of the drug acceptable despite its risks. Class X: Studies in animals or humans have demonstrated fetal abnormalities, or there is evidence of fetal risk based on human experience, and the risk of the drug clearly outweighs any possible benefit. These drugs are contraindicated in pregnancy.

Cystic Fibrosis

Cystic fibrosis (CF), present in about 1 in 1500 whites and 1 in 17,000 blacks, is a common genetic disease. With improved therapy, median survival has now increased to 37 years.³⁰ Up to 4% of female CF patients between the ages of 17 and 37 may be pregnant at any time,³¹ despite the frequent infertility of women due to delayed sexual development. Pregnancy in CF patients, as might be anticipated, has been associated with adverse fetal and maternal outcomes.^{32,33} Several recent small case series have demon-

strated good maternal and neonatal outcome in women with CF.³⁴⁻³⁶ Premature delivery was more common in women with worse baseline FEV₁, and gestational diabetes was common. In a large U.S. review of 680 gravid women with CF enrolled in the U.S. Cystic Fibrosis Foundation National Patient Registry, from 1985 to 1997, survival was actually better in the gravid group than in the matched 3327 control patients with CF.³⁷ Women with CF who became pregnant had higher predicted percentages of FEV₁ and higher weights. Pregnancy was not clearly harmful in any subgroup, after severity adjustment for age, *Pseudomonas aeruginosa* colonization, pancreatic function, and FEV₁. In another case-control study, pregnancy had little effect on patients with stable CF, although poor outcomes were seen in those with severe disease.³⁸ As might be anticipated, most studies suggest that risk stratifies according to severity of illness.^{33,38} Declines in pulmonary function tend to mirror severity-adjusted control subjects, and clearly CF patients require substantially more care and have more visits to physicians when pregnant than when not.³⁹ Prepregnancy counseling, particularly for women with more severe disease, is essential in limiting excessive maternal and fetal risk.

INFECTIOUS DISEASES

Bacterial Pneumonia

Pneumonia is a leading cause of maternal and fetal morbidity and mortality.⁴⁰⁻⁴² Maternal mortality from pneumonia in nonimmunocompromised hosts ranged from 0% to 4% in series published since 1980.⁴⁰⁻⁴² The reported incidence varies widely, from 0.4 to 2.7 per 1000 deliveries,⁴³ but may not be higher than that in the general population. One report, however, indicated that pneumonia may be increasing in incidence, with *human immunodeficiency virus* (HIV) infection and chronic disease the major risk factors.⁴⁰ Postpartum pneumonia may develop in the first 6 weeks after delivery and is more common after Cesarean section.⁴⁴

Pregnancy increases the risk for major complications of pneumonia. In the series by Madinger and colleagues,⁴² of 25 patients culled from 25,000 deliveries, 40% suffered major complications, including five intubations, two empyemas, one pneumothorax, and one pericardial tamponade. Similarly, in the series by Briggs and associates,⁴⁵ 7 of 34 patients required mechanical ventilation, and 2 died. The *Pneumonia Severity Index* (PSI)⁴⁶ used to identify severity of pneumonia for hospital admission does not appear to perform well in the obstetric population, underestimating the need for hospital admission.⁴⁷ Pneumonia increases the risk of preterm labor from 4% to 44%.⁴⁰⁻⁴² The small-for-gestational-age rate is as high as 12%,⁴⁰ and intrauterine and neonatal death rates have ranged from 1.9% to 12.0%.^{41,42} In all series, underlying chronic illness in the mother has been a powerful predictor of adverse outcome in both fetus and mother.

Pneumonia in pregnancy is most commonly bacterial in origin; the microbiologic spectrum mirrors community-acquired pneumonia, with *Streptococcus pneumoniae* and *Haemophilus influenzae* the most common organisms.⁴⁰⁻⁴² Other common organisms include *Mycoplasma pneumoniae* and *Chlamydia pneumoniae*. As in other community-acquired

pneumonias, the causative agent is identified in only about half of the cases. Unfortunately, the diagnosis of pneumonia is frequently delayed because of reluctance to obtain a chest radiograph; a posteroanterior radiograph performed with a grid and a peak voltage of 90 to 120 kV exposes the mother to 5 to 30 mrad but the fetus to 100 times less, or about 300 μ rad.⁴⁸ A lateral chest radiograph produces greater maternal exposure (150 to 250 mrad) but is usually not required.⁴⁸ The hazard to both fetus and mother of delaying the diagnosis greatly exceeds the risk of this small radiation dose. Antibacterial therapy is similar to treatment in the nonpregnant patient, although tetracyclines, quinolones, and metronidazole should be avoided if possible.⁴⁸ Erythromycin, azithromycin, and β -lactam antibiotics are preferred because of their favorable safety profile (see Table 96-1).

Viral Pneumonia

Viral pneumonia remains a serious concern in pregnancy. In the influenza pandemic of 1918, the maternal rate of mortality from pneumonia was as high as 50%. In the epidemic of 1957, pregnant women accounted for 10% of fatalities, and about half of the women of childbearing age who died were pregnant.⁴⁹ Since then, the maternal mortality rate from influenza A and B pneumonia has been relatively low but still much higher than that in the general population. Because of this, the *Centers for Disease Control and Prevention* (CDC) recommends inactivated influenza vaccine in otherwise healthy women during the second and third trimesters of pregnancy.⁵⁰ Although influenza virus does cross the placenta, current opinion holds that it is not likely to be teratogenic to the fetus, despite isolated reports that link influenza with neural tube and other malformations. Amantadine has been used in pregnancy successfully, both as treatment and as prophylaxis, although there have been case reports of cardiovascular defects noted after first-trimester use; and there is considerable influenza viral resistance to the drug.

In the spring of 2009, a previously unrecognized strain of influenza A (H1N1) virus emerged and quickly spread around the world. Reports of clinical experiences with large numbers of hospitalized patients with H1N1 influenza in Australia-New Zealand and throughout the United States confirm that pregnancy confers a high risk of serious disease and appreciable mortality.^{51,52} Early treatment of pregnant women and women up to 2 weeks postpartum with oseltamivir or zanamivir appears to be beneficial.⁵³ Pregnant women are also strongly urged to be vaccinated with the monovalent inactivated injectable H1N1 vaccine—not with the live attenuated vaccine.⁵⁴

Varicella pneumonia, caused by a virus of the DNA herpesvirus group, has also been linked to particularly adverse outcomes during pregnancy. Haake and coworkers⁵⁵ report an increased incidence of pneumonitis in pregnant women with primary varicella infection and a 35% mortality rate in this group (over a time period dating back to 1964), compared with 10% in other adults. Data are conflicting, and not all prospective studies have confirmed an increased incidence or mortality in pregnancy.⁴⁸ Treatment with acyclovir does appear to reduce mortality in gravid patients and should be used as therapy for active disease.⁵⁶ Use of *varicella-zoster immune globulin* (VariZIG) should be consid-

ered within 96 hours for susceptible pregnant women who have been exposed to varicella. Administration of VariZIG reduces but does not abolish risk for fetal infection or congenital varicella syndrome, and it is effective in preventing complications of varicella in the mother. Patients should be evaluated similarly to other adults, and a decision made to administer the immune globulin on the basis of immune status, type of exposure, and health status. The currently licensed attenuated live vaccine against varicella is contraindicated in pregnancy.

Severe acute respiratory syndrome (SARS), due to a novel coronavirus (HuCoV-SARS), causes pneumonia and *acute respiratory distress syndrome* (ARDS), with respiratory failure in 15% of patients and a mortality rate of 8% to 30%.^{57,58} Although data are limited, pregnant women appear to do worse than nonpregnant patients, with four of seven patients requiring ventilatory support in one series.⁵⁹ SARS infection adversely affects pregnancy, with miscarriage, fetal distress, and intrauterine death reported, presumably related to hypoxemia.

Fungal Pneumonias

Fungal pneumonias are uncommon in pregnancy. Although there is no evidence that blastomycosis and histoplasmosis are more severe during pregnancy, it does appear that coccidioidomycosis is more likely to disseminate in pregnancy.⁶⁰ In the southwestern United States, about 1 in 5000 pregnancies is complicated by *Coccidioides immitis* (see eFig. 37-7).⁶¹ Dissemination is highly probable during the third trimester and has been related to both subtle impairment of cell-mediated immunity and a stimulatory effect of progesterone and 17- β -estradiols on fungal proliferation.⁶² Amphotericin is the accepted therapy for disseminated coccidioidomycosis; azoles administered in the first trimester have been associated with branchial cleft abnormalities and should be used only after delivery.

Tuberculosis

Tuberculosis does not appear to be more common or severe in pregnancy. However, presentation may be atypical and disease is often extrapulmonary.⁶³ Diagnosis may be delayed by a reluctance to perform appropriate imaging studies. Pregnancy does not alter reactivity to tuberculin skin testing, and hence the test should be performed in the recommended groups during pregnancy. Interferon- γ -release assays are also an acceptable means of testing for tuberculous infection (see Chapter 35). Asymptomatic patients with positive skin tests should have their chest radiograph deferred until after 16 weeks of gestation. Symptomatic patients with positive skin tests merit chest radiographs regardless of gestational stage. Isoniazid, rifampin, and ethambutol have acceptable safety profiles in pregnancy and are part of the standard treatment regimens advised by the CDC and American Thoracic Society for pregnant women.⁶⁴ There is less collective experience with pyrazinamide, but this drug is recommended for use in pregnancy by the World Health Organization.⁶⁴ Worldwide data are accumulating, and pyrazinamide appears to be emerging as a drug that can be considered for treating multidrug-resistant tuberculosis and for HIV-infected women. Streptomycin, by contrast, is clearly associated with congenital deafness and is contraindicated during pregnancy.

PULMONARY EDEMA AND PULMONARY VASCULAR DISEASE

Gravid women are at special risk for pulmonary edema for a variety of reasons, including the hypervolemia and high cardiac output of pregnancy, the occasional need for tocolytic drugs that affect the vascular bed, and the unique vascular and endothelial disorders of pregnancy.

Among these effects, it is noteworthy that colloid osmotic pressure diminishes during pregnancy, although the effect on transcapillary pressure gradients is partially offset by a decrease in interstitial fluid colloid osmotic pressure (as explained in Chapter 6).⁶⁵ Etiologically, underlying cardiac disease, use of tocolytic drugs, fluid overload, and preeclampsia are the most common causes for acute pulmonary edema in pregnancy.⁶⁵

Increased Pressure (Cardiogenic) Pulmonary Edema

The cardiovascular adaptations to pregnancy have already been summarized. Their effects on underlying cardiac disorders are predictable. Stenotic valvular lesions are particularly poorly tolerated.⁶⁶ Of these, mitral stenosis is the most common symptomatic valvular disease in pregnancy and frequently presents with pulmonary edema, not only during gestation but also immediately postpartum, because of the large shifts in intravascular volume associated with delivery. The gradient across a stenotic mitral valve is augmented by the increases in blood volume, cardiac output, and heart rate that take place during gestation and the puerperium. In aortic stenosis, the increase in cardiac output required for pregnancy worsens the gradient across the valve. As a compensatory mechanism, the left ventricular end-diastolic volume increases, but the low SVR impairs coronary artery filling during diastole and can precipitate ischemic syndromes. The reduction in SVR of pregnancy mitigates the consequences of mitral and aortic regurgitation and of the left-to-right intracardiac shunts of endocardial cushion defects but worsens the consequences of Eisenmenger syndrome and uncorrected tetralogy of Fallot. Depending on the cardiac disorder, perturbations induced by pregnancy can alter fractional shunts, induce hypoxemia, or precipitate pulmonary edema.

A special problem of pregnancy is peripartum cardiomyopathy, a disorder that develops in 1 of 1300 to 15,000 deliveries, may present with congestive heart failure, and is associated with a special propensity for both pulmonary and systemic embolization during the last month of pregnancy and for up to 5 months thereafter.⁶⁷ Standard therapy for heart failure, including β -blockers, diuretics, angiotensin-converting enzyme inhibitors and blockers, are usually effective, but sometimes implantable defibrillators and even left ventricular assist devices and heart transplantation are required.^{67,68}

Tocolysis-Associated Pulmonary Edema

The use of drugs such as β_2 -sympathomimetic agents to retard premature labor is uncommon in current obstetric practice but, in the past, was associated with a 0% to 4% incidence of pulmonary edema.⁶⁹ The etiology of this disorder is controversial and likely multifactorial in nature,

related to myocardial effects, vascular permeability impairment, and fluid retention. It usually presents after at least 24 hours of β -adrenergic therapy, with relatively acute onset of dyspnea and pulmonary edema seen on chest radiographs. Simple discontinuation of β -adrenergic therapy often results in rapid improvement; whether diuretics need to be given is unresolved, but furosemide is usually administered. Pulmonary edema has also complicated tocolysis performed with calcium channel blockers.⁷⁰

Pulmonary Edema Associated with Preeclampsia

About 2.9% of patients with preeclampsia or eclampsia develop pulmonary edema.⁷¹ The spectrum of hemodynamic findings associated with pregnancy-induced hypertension and preeclampsia is wide but, in general, left ventricular preload is normal or low, afterload is high, and cardiac output is normal or low (Fig. 96-3). Systolic and diastolic function may also be impaired.⁷² The pulmonary edema commonly first presents in the postpartum period,^{71,72} reflecting fluid administration at delivery. Low colloid oncotic pressure and abnormal vascular permeability likely contribute as well. Hemodynamic monitoring of these patients is probably warranted if oliguria complicates the picture.

Pulmonary Embolism

Pulmonary embolism is a leading cause of maternal mortality,⁷³ accounting for 9% of 95 pregnancy-related deaths in a large health care delivery system in the United States between 2000 and 2006.⁷³ Even though the risk for venous thromboembolism in pregnant women is about five times as great as in age-matched and sex-matched nongravid controls, it is still relatively infrequent. A Danish population-based study of 63,000 deliveries found a cumulative incidence of 0.85 in 1000 deliveries from 1984 to 1994.⁷⁴ In this study, the incidence of detected venous thromboembolism increased to 1.23 in 1000 deliveries after the introduction of ultrasonography, demonstrating that its reported incidence may depend on the adequacy of diagnostic procedures employed. Other studies have reported rates of 0.6 to 2 per 1000 pregnancies.⁷⁵ The risk for thrombosis is increased in pregnancy, partly because of the increase in coagulation factors, particularly V, VIII, X, and von Willebrand factor antigen, and partly because of a marked fall in protein S.⁷⁶ Venous stasis, an important contributor to thrombosis, is caused by uterine compression of the inferior vena cava and the left iliac vein. Local trauma to pelvic veins at the time of delivery probably accounts for the peak incidence of thromboembolism in the postpartum period, especially after cesarean section. Specific risk factors for thromboembolism include previous thromboembolism during pregnancy or while taking oral contraceptives, prolonged bed rest, a complicated or cesarean delivery, age, thrombophilia, obesity, and smoking. The inherited defects include deficiencies of antithrombin, protein S, protein C, factor V Leiden, and prothrombin G20210A.⁷⁶ Antiphospholipid syndrome is an acquired thrombophilia. Previous thromboembolism or antithrombin deficiency warrant prophylactic heparin administration throughout pregnancy, now commonly accomplished with *low-molecular-weight heparins* (LMWHs) due to their safety and decreased risk of heparin-induced osteopenia and thrombocytopenia.

Figure 96-3 Pregnancy-induced hypertension. The spectrum of hemodynamic profiles is shown for 45 women with severe pregnancy-induced hypertension, one of the disorders sometimes complicated by pulmonary edema. Pulmonary edema in pregnancy-induced hypertension usually does not reflect simple volume overload. (From Cotton DB, Lee W, Huhta JC, et al: Hemodynamic profile of severe pregnancy-induced hypertension. *Am J Obstet Gynecol* 158:523–529, 1988.)

Clinical diagnosis of deep venous thrombosis during pregnancy and the puerperium is even more difficult than in the nonpregnant patient because of the peripheral edema associated with pregnancy and the asymmetrical compression of the left-sided common iliac vein by the gravid uterus. The initial diagnostic test should be duplex ultrasonography (combined real-time B-mode compression ultrasonography plus Doppler venous ultrasonography). In the patient with high clinical suspicion but a negative test, a repeat examination at 5 to 7 days may be valuable. When venous thrombosis of the lower extremity is documented, it is usually left sided, as it was in 84 of 96 (88%) cases reported by Chan and colleagues.⁷⁷

The diagnosis of pulmonary embolism in pregnant women is relatively straightforward. Both ventilation-perfusion scanning and *computed tomography* (CT) pulmonary angiography can be performed during pregnancy in a modified fashion. Estimated fetal radiation exposure for a perfusion scan is about 0.011 to 0.022 cGy (11 to 22 mrad), and simply halving the perfusion dose is standard practice in pregnancy, without greatly impairing resolution.⁷⁸ There is no need for the ventilation portion of the study if perfusion is normal. CT pulmonary angiography is an acceptable imaging modality and is associated with similarly low radiation doses to the fetus (Fig. 96-4).^{78,79} However, a risk to consider is the potential carcinogenic effect of radiation exposure to the mother's breasts,^{78,80} although shielding can reduce exposure (see Fig. 96-4B). Pulmonary angiography, when performed by the brachial route, exposes the fetus to only about 0.050 cGy

(50 mrad),⁸¹ but this procedure has a limited role in pregnancy. Such levels of exposure are not believed to cause teratogenicity, which is associated with exposure of greater than 5 to 10 cGy (5 to 10 rad). However, an increased incidence of childhood leukemia has been documented with lower fetal radiation exposure, in the range of 1 to 5 cGy (1 to 5 rad). A comparison of lung scintigraphy and pulmonary CT angiography concluded that the former method was more accurate than the latter for diagnosing pulmonary embolism during pregnancy.⁸² Ventilation-perfusion scanning in pregnancy, due to the patient's younger age and lack of comorbidity, is associated with a lower incidence of intermediate scans and higher rate of normal scans.⁸³ CT angiography may more often be technically suboptimal, due to the increased cardiac output in pregnancy.⁸⁴ *Magnetic resonance imaging* (MRI) with gadolinium contrast also has promise because it can image pelvic and lower extremity veins, as well as the pulmonary arteries, and it has little contrast-associated toxicity. Its widespread use will require increased availability of ultrafast scanners and more evaluation of its accuracy.

Venous thromboembolism in pregnancy is treated with heparin because warfarin crosses the placenta and causes nasal, ophthalmologic, and central nervous system abnormalities in the fetus. LMWH appears to be safe in pregnancy and, compared with unfractionated heparin, is associated with fewer adverse effects.^{85,86} LMWH is preferred over unfractionated heparin in pregnancy, using a weight-adjusted dosing regimen.⁸⁷ Weight gain in pregnancy makes formulaic dosing less reliable, and some authors also

Figure 96-4 Dose-reduction methods for chest CT in the pregnant patient. **A**, Scout view before the CT acquisition shows an “internal barium shield” (arrows) created by having the patient swallow a dilute mixture of barium and water several minutes before CT scanning. The barium distributes within the stomach and proximal small bowel and attenuates internal maternal radiation that may otherwise expose the fetus. A lead apron (arrowheads) also reduces fetal radiation exposure. **B**, Axial chest CT pulmonary angiogram obtained with manual reduction of both the tube current and tube voltage shows excellent vascular opacification, providing high-quality assessment for pulmonary embolism and other thoracic disorders. A maternal breast shield (arrowheads) has also been placed; these shields selectively filter low-energy x-ray photons that would otherwise deposit preferentially in maternal breast tissue, significantly contributing to maternal breast radiation exposure. (Courtesy Michael Gotway, MD.)

advocate titrating the dose to achieve anti-factor X levels of 0.5 to 1.24 units/mL 4 hours after injection.^{85,86} However, the lack of good data and lack of correlation of levels with efficacy or complications makes routine monitoring difficult to justify.⁸⁷ LMWH treatment is usually given for at least 6 weeks postpartum (for a minimum total duration of therapy of 3 months). LMWH should be held 24 hours before induction, cesarean section, or neuraxial anesthesia (for twice-daily dosing) or after a 50% dose the morning before delivery for daily dosing regimens.⁸⁷ Postpartum, warfarin can be given safely during lactation.

Thrombolytic therapy has been used successfully in life-threatening thromboembolism during pregnancy, with a complication rate similar to that in nonpregnant women.⁸⁸

Figure 96-5 Amniotic fluid embolism. Interstitial pulmonary capillaries filled and expanded by eosinophilic fetal squamous cells (arrows) from a case of amniotic fluid embolism in a 39-year-old woman who succumbed within 4 hours of delivery. (H&E stain; original magnification $\times 200$). *Insert:* High-molecular-weight keratin stain, CK5/6 staining the intravascular fetal squamous cells (shown by brown color)(original magnification $\times 400$). (Courtesy Dr. Gerald Berry, Stanford University.)

Amniotic Fluid Embolism

Small amounts of amniotic fluid may enter the circulation during uncomplicated pregnancy but rarely cause the catastrophic syndrome of amniotic fluid embolism.⁸⁹ The reported incidence varies from 2 to 6 per 100,000 pregnancies, the variation being largely dependent on the method of case identification.⁹⁰ The onset is usually during labor and delivery or immediately after uterine manipulation, with development of severe dyspnea, hypoxemia, and then seizures and cardiovascular collapse or arrest. If the patient survives the initial insult, disseminated intravascular coagulation and ARDS usually supervene.⁹¹ Risk factors include older maternal age, induction of labor, high parity, cesarean section, low uterine segment laceration, and meconium staining of amniotic fluid.⁸⁹⁻⁹¹ Abruptio placentae is present in 50% of cases, and fetal demise in 40%.⁹¹ The maternal mortality rate has been as high as 86%,⁹² but a more recent report suggests a mortality of 11% to 43%.⁹⁰ Overall, amniotic fluid embolism may account for 14% of all maternal deaths.⁷³

In a U.S. registry of cases, 78% of the patients with amniotic fluid embolism had ruptured membranes, and several had just undergone intrauterine procedures,⁹³ clearly implicating traumatic opening of uterine vessels in the pathogenesis. The exact quantity or constituents of amniotic fluid required to initiate the syndrome is unknown. Pathologically, fetal squamous cells are found in the maternal pulmonary circulation at autopsy (Fig. 96-5) but, even in symptom-free patients, fetal cells may be aspirated from pulmonary artery catheters placed for other reasons.⁹⁴ Hemodynamically, the process is often biphasic, with pulmonary hypertension initially, followed by left ventricular failure.^{95,96} These changes may be caused by leukotrienes and arachidonic acid metabolites, particularly prostaglandin F_{2a} , which appear in amniotic fluid during labor. An immunologic basis for some of the changes seems likely because women with male fetuses are more likely to acquire the disorder.⁹⁰ Clark and associates⁹³ seized on the similarities to anaphylaxis and suggested that the disorder be renamed

Figure 96-6 Amniotic fluid embolism. **A**, Frontal chest radiograph in a patient who developed shortness of breath and cardiovascular instability during delivery shows multifocal, poorly defined opacities (arrows) along the bronchovascular bundles, distributed in the mid and lower lungs bilaterally. **B–E**, Axial chest CT pulmonary angiogram obtained for pulmonary embolism evaluation, displayed in lung windows, shows multifocal nodular appearing ground-glass opacities (arrowheads), somewhat more confluent in the right middle lobe (arrow). No features to suggest increased pressure edema, such as pleural effusion or interlobular septal thickening, are present, and no pulmonary embolism was detected. The CT features are consistent with an acute lung injury pattern. (Courtesy Michael Gotway, MD.)

anaphylactoid syndrome of pregnancy. A small study did not demonstrate evidence of mast cell degranulation but suggested a role for complement activation.⁹⁷

On imaging studies, affected patients usually develop bilateral parenchymal opacities consistent with pulmonary edema associated with increased permeability lung injury (Fig. 96-6). Treatment consists of supportive care for the associated disseminated intravascular coagulation and left ventricular and respiratory failure. The fetus should be promptly delivered. In cases of maternal demise, emergency postmortem or periresuscitative cesarean section is warranted, as it is in other instances of cardiopulmonary resuscitation in pregnancy.⁹⁸

Arteriovenous Malformations

Pulmonary arteriovenous malformations may expand during pregnancy because of hormonal changes, the increase in blood volume, and venous distensibility.⁹⁹ This increases the likelihood of bleeding, with life-threatening complications in about 1% of pregnant women with hereditary hemorrhagic telangiectasia.^{100,100a} Embolization and surgical management have been utilized successfully during pregnancy.

Air Embolism

Occasionally, venous air embolism can happen during pregnancy, presumably through the subplacental venous sinuses.¹⁰¹ This disorder has been clearly documented during labor and delivery, during cesarean sections and abortions, in patients with placenta previa, and in those engaging in orogenital sex during pregnancy or the early puerperium.

ACUTE LUNG INJURY IN PREGNANCY

Aspiration Pneumonitis

Since Mendelson's¹⁰² original report of 66 cases of gastric aspiration in 44,016 deliveries between 1932 and 1945 (an incidence of 0.15%), aspiration has continued to be

a major cause of maternal morbidity and mortality. Increased intra-abdominal pressure due to the gravid uterus, the inhibitory effect of progesterone on the tone of the esophageal sphincter, and the assumption of the supine position for delivery all contribute. Eating during or just before labor increases the volume of emesis.¹⁰³ Aspiration of gastric contents with pH 2.5 or lower is known to cause chemical pneumonitis and increased permeability edema. Both in Mendelson's original report and today, about two thirds of cases of aspiration take place in the delivery suite. Emergency endotracheal intubation of patients with obstetric crises is particularly difficult,¹⁰⁴ and intubation in the delivery suite fails at a rate eight times that in the general surgical population.¹⁰⁵ To minimize the chance of acid aspiration at intubation, oral administration of histamine-2 blockers with antacids before intubation,¹⁰⁶ in conjunction with a formal airway assessment, is desirable. Identified risk factors in intubation include a high Mallampati class indicating poor visibility of the posterior pharynx, a short neck, protruding maxillary incisors, and a receding mandible.¹⁰⁷

Acute Respiratory Distress Syndrome

ARDS is more common in pregnancy than in the general population, with an incidence of 1/6000 deliveries.¹⁰⁸ In one obstetric intensive care unit, ARDS was the leading cause of maternal death during a 6-year period.¹⁰⁹ The three most common nonobstetric causes are pneumonia, sepsis, and aspiration. The 2009 influenza A (H1N1) epidemic resulted in a significant increase in the incidence of ARDS in pregnancy, generating numerous publications on the epidemiologic and management issues. Australian investigators described a series of pregnant women treated with extracorporeal membrane oxygenation with reasonable outcome.¹¹⁰ Common obstetric causes of ARDS include chorioamnionitis, amniotic fluid embolism (see Fig. 96-6), and trophoblastic embolism.¹¹¹ Ventilator management is unaltered in pregnancy and, although pregnancy was an exclusion criterion in the ARDS Network studies, the clear benefit in nonpregnant patients supports the use of

low-volume ventilatory strategies in pregnant patients, with tidal volume (6 mL/kg) based on the patient's ideal weight.^{111,112} The prognosis also appears to be similar to the nonpregnant patient,¹¹³ although ARDS outcome is dependent on the underlying etiology.

OTHER RESPIRATORY DISEASES IN PREGNANCY

Obstructive Sleep Apnea

Pregnancy may be complicated by *obstructive sleep apnea* (OSA), potentially adversely affecting both mother and fetus.¹¹⁴ Although upper airway edema may potentiate obstructive events, apnea and hypopnea are uncommon in pregnancy because of the respiratory stimulatory effect of progesterone.¹¹⁵ OSA usually develops in obese patients, precipitated by the airway mucosal edema and vascular congestion that accompany pregnancy. OSA is associated with preeclampsia and gestational diabetes.^{115,116} Nocturnal hypoxemia may produce poor fetal growth, although snoring alone is not associated with fetal risk.¹¹⁷ Pregnant women with documented obstructive sleep apnea are at increased risk of developing preeclampsia and preterm birth.¹¹⁸ Treatment with nasal continuous positive airway pressure is safe and effective for women with documented significant OSA.¹¹⁵

Interstitial Lung Disease

Interstitial lung disease is usually seen in patients older than those in their childbearing years.¹¹⁹ When interstitial disease exists in pregnant women, the reduced diffusing capacity may cause difficulty in meeting the increased oxygen consumption requirements of pregnancy. Associated pulmonary hypertension, regardless of its causes, carries significant risks because cardiac output increases during pregnancy. Few data exist on the management and outcome in these patients, but restrictive lung disease appears reasonably well tolerated in pregnancy.^{120,120a} Lymphangioleiomyomatosis and systemic lupus erythematosus may worsen as a result of pregnancy.¹¹⁹ Some drug therapy used for interstitial lung disease may be acceptable during pregnancy (e.g., prednisone, azathioprine), but other therapy (e.g., cyclophosphamide, rituximab, mycophenolate mofetil) is usually avoided.¹¹⁹

Pleural Disease

Pleural effusions may accompany obstetric complications such as preeclampsia and choriocarcinoma, but many women with normal pregnancies develop small, asymptomatic pleural effusions in the postpartum period.¹²¹ They develop as a result of the increased blood volume and reduced colloid osmotic pressure in pregnancy, as well as from impaired lymphatic drainage due to repeated Valsalva maneuvers during labor. Moderate-size effusions or the presence of symptoms should prompt a full clinical evaluation. The Valsalva maneuvers of labor may also produce spontaneous pneumothorax and pneumomediastinum, particularly in patients with predisposing conditions such as asthma. This diagnosis should be considered in women who develop chest discomfort and dyspnea during, or immediately following, delivery.

Figure 96-7 Pulmonary endometriosis. Wedge resection of right upper lobe subpleural nonencapsulated lesion in a 43-year-old woman with a history of pelvic endometriosis and recurrent pneumothoraces with menstrual cycles. (H&E stain; original magnification $\times 40$). *Insert:* The discrete nodule is composed of endometrial stromal cells admixed with endometrial glands. (H&E; original magnification $\times 200$.) GYNECOLOGIC DISORDERS AND THE LUNGS

CATAMENIAL PNEUMOTHORAX

Lillington and colleagues¹²² introduced in 1972 the term *catamenial pneumothorax* to describe the already reported phenomenon of spontaneous pneumothorax within 24 to 72 hours after onset of menses. It appears to account for about 2.8% to 5.6% of spontaneous pneumothoraces in women,^{123,124} most often affecting women in the third or fourth decade of life. About 30% to 60% of cases are attributable to thoracic endometriosis, as judged by inspection at thoracotomy (Fig. 96-7)¹²⁵; other cases have a more obscure etiology, however, so a number of theories have been advanced. The first theory is that, during menstruation, the absence of the normal cervical mucus plug permits an open connection between ambient air and the abdominal cavity through the uterus and fallopian tubes.¹²⁴ Air can move transdiaphragmatically through right-sided diaphragmatic fenestrations into the pleural space, as it sometimes does during abdominal laparoscopy,¹²⁶ accounting for the condition's right-sided predominance.¹²⁴ A second theory is that high levels of prostaglandin F_{2a} during menstruation cause bronchospasm with attendant air trapping and pneumothorax, but wheezing is not a common symptom of this disorder. A third theory is that pleural blebs or bullae are more susceptible to rupture during menstruation because of hormonal changes,^{124,125} but visceral pleural leaks are rarely found at surgery (see also Chapter 81 for a full discussion).

For cases of endometriosis-associated pneumothorax, a trial of gonadotropin-releasing hormones is warranted if the phenomenon is repetitive but not life-threatening. Oral contraceptives, other progestational agents, and tubal

ligation have also been used with some success. For cases not clearly associated with systemic endometriosis, thoracoscopy during menstruation serves to define the etiology and can be used to achieve pleurodesis.¹²⁶

ENDOMETRIOSIS

Endometriosis probably affects about 10% of women, shows no clear ethnic differences in prevalence, and is most commonly diagnosed at 30 to 34 years of age.¹²⁷ Although pelvic pain, dysmenorrhea, and infertility are its predominant manifestations, atypical locations, including diaphragmatic, pleural, and endobronchial sites, have been documented. As described previously, endometriosis can result in recurrent catamenial pneumothorax, which is its most common thoracic presentation (see Fig. 96-7). In one review of 110 cases with thoracic endometriosis, catamenial pneumothorax was the presenting symptom in 73% of cases, followed by hemothorax in 14% and hemoptysis in 7%.¹²⁷ It also has been associated with right-sided pleural pain, pleuritic effusions, and hemothorax. Inspection at thoracotomy or thoracoscopy typically reveals blue-brown nodules on the pleural surface, sometimes in a “gunshot” distribution.¹²⁸ The absence of known pelvic endometriosis does not exclude the diagnosis because only 20% to 70% of patients have associated pelvic disease. The diagnosis is suspected on clinical grounds because neither CT nor endoscopy is specific.¹²⁹ Rarely, the endometriosis deposits are found in lung parenchyma, accounting for the catamenial hemoptysis. Most pleural and diaphragmatic disease is thought to arise from transdiaphragmatic spread from retrograde menses, even when abdominal disease is not evident. Massive ascites is sometimes related, although only 27 cases have been reported.¹³⁰ Pneumothoraces may be attributed to cyclical sloughing of tissue on key surfaces, such as the visceral pleura,¹³¹ or to air trapping from airway involvement or compression.¹²² Pulmonary parenchymal disease may be embolic in origin, as is presumed to be in the case of central nervous system endometriosis. The diagnosis can be established only by biopsy showing the characteristic ectopic endometrial glands in involved sites. Medical therapy consists of progestational agents or gonadotropin-releasing hormones; surgical approaches include excision, local laser ablation, or pleurodesis.

LYMPHANGIOLEIOMYOMATOSIS

Lymphangioleiomyomatosis (LAM) is a rare disorder that afflicts predominantly premenopausal women.^{132,133} The most common presenting event is a pneumothorax, reported in 86.5% of patients in the National Heart, Lung, and Blood Institute registry.¹³² It is fundamentally a disorder of smooth muscle proliferation that results in functional obstruction of vessels, lymphatics, and airways. (See Chapter 69 for a complete discussion of LAM.) Involvement of pulmonary vascular structures is responsible for the hemoptysis, whereas lymphatic obstruction accounts for the chylous effusions. Mediastinal and retroperitoneal lymphatic proliferation may be a feature of the disease as well. LAM is also associated with renal angiomyolipomas, another hamartomatous disorder, and with tuberous scler-

osis. Conventional therapy has included oophorectomy or progestational agents, mainly medroxyprogesterone acetate. Lung transplantation has been performed in more than 60 patients with this disorder, but it has clearly recurred in some of them. Sirolimus, in a trial in patients with angiomyolipomas and tuberous sclerosis complex or LAM, showed ameliorative effects on lung function and volume of angiomyolipomas, presumably by suppressing signaling pathways involved in products of the defective genes.¹³⁴ LAM is now included in the group of perivascular epithelioid cell tumors, whose molecular pathology is being elucidated, opening the possibility of targeted therapy.¹³⁵

TROPHOBLASTIC EMBOLIZATION

Trophoblastic embolism is a rare complication of hydatidiform mole, an abnormal type of pregnancy in which nonviable fertilized tissue grows in the uterus. In one series, only 2.6% of 189 patients with hydatidiform mole had an embolic event, so most episodes of respiratory distress in such patients are not caused by embolic events but, rather, pulmonary edema, anemia, or another complicating event.¹³⁶ Embolization, when it happens, is most common at the time of evacuation of the mole. Chorionic neoplasms that arise during gestation are suggested by a large discrepancy between gestational date and uterine size and should be evaluated by transvaginal ultrasonography.¹³⁷

OVARIAN HYPERSTIMULATION SYNDROME

The use of exogenous gonadotrophins to stimulate ovulation for in vitro fertilization has been associated with pulmonary complications.¹³⁸ This ovarian hyperstimulation syndrome usually manifests with ovarian cysts, bilateral pleural effusions, ascites, and intravascular volume depletion. Hypovolemic shock, renal failure, and ARDS may result. Pulmonary embolism and upper limb or superior venal caval thrombosis may result from the hypercoagulable state induced by estrogens and intravascular volume depletion. The mechanism of the effusions is unclear but is likely related to increased permeability due to release of vasoactive mediators, of which vascular endothelial growth factor appears to be the most important.¹³⁹ Evidence points to mutations in the follicle-stimulating hormone receptor as etiologic in at least some cases.¹⁴⁰ Treatment is supportive and involves maintaining intravascular volume, thoracentesis when required for respiratory compromise from abundant pleural effusion(s), and thromboprophylaxis.

Key Points

- Normal pregnancy is associated with profound alterations in respiratory and cardiovascular physiology, which—although designed for maternal and fetal well-being—may exacerbate underlying cardiopulmonary conditions or cause new ones.
- Major physiologic perturbations found in normal pregnancies include (1) an increase in central drive to breathe, with resulting changes in P_{CO_2} (28 to 32 mm Hg) and pH (7.40 to 7.47); and (2) an increase in both

maternal blood volume, of about 2 L (40%), and cardiac output, after 25 to 32 weeks of gestation, of 30% to 45%.

- The most common pulmonary disorder of pregnancy is asthma, but the effects of pregnancy on asthma are variable: it worsens, improves, or remains unchanged in roughly one third of afflicted women.
- The risks of poorly controlled asthma for both mother and fetus during pregnancy far outweigh the risks of drug therapy. Some standard drugs are safer than others (see [Table 96-1](#)) and should be selected whenever possible.
- Cystic fibrosis and infectious pneumonias have all been linked with adverse fetal and maternal outcomes, the risk of which depends largely on the severity of the complicating disorder. Prepregnancy counseling and avoidance of certain antimicrobial drugs (as noted in [Table 96-1](#)) are strongly recommended.
- Pulmonary edema may develop during pregnancy in women with underlying heart disease, especially valvular stenosis, cardiomyopathy, and preeclampsia. Because the causative mechanisms differ, so does specific therapy.
- Pulmonary embolism is a leading cause of maternal mortality. When indicated during pregnancy, low-molecular-weight heparins are safe for both treatment and prevention; warfarin is contraindicated. Ventilation-perfusion imaging, CT pulmonary angiography, and magnetic resonance imaging can be used as needed.

INTRODUCTION

Gas exchange between the atmosphere and the human body depends not only on the lungs but also in large part on the function of the “ventilatory pump,” which consists of the respiratory control centers located in the brain, the bony rib cage, diaphragm, and intercostal, accessory, and abdominal muscles. A wide variety of neuromuscular disorders can result in dysfunction of the ventilatory pump that in turn can lead to respiratory failure, pneumonia, and even death. Breathing disorders are recognized as the leading cause of mortality in neuromuscular disease,^{1,2} and appropriate interventions can prevent complications and prolong life in individuals with neuromuscular disease affecting the respiratory system.³ Diseases of the chest wall are discussed in Chapter 98.

FUNCTIONAL ANATOMY OF THE RESPIRATORY SYSTEM

The ventilatory pump is designed to bring oxygen into the body to fuel energy generation and remove carbon dioxide as a waste product of cellular metabolism. The system is made up of the cortex of the brain that controls voluntary breathing; the brain stem, which is involved with automatic breathing; the spinal cord and motor neurons that transmit nerve impulses; the respiratory muscles that are the effectors of the system; and a complex system of feedback receptors and nerves that regulate ventilation (Fig. 97-1). The system is remarkably flexible and can precisely maintain carbon dioxide and acid-base balance despite encountering large variations in metabolic demands that result from the activities of daily living. The following is a discussion of each of the components of this complex network.

CENTRAL NERVOUS SYSTEM

Voluntary Breathing Controllers

Voluntary breathing is controlled by signals from the cerebral cortex. Centers located within the parietal cortex send

volitional signals that initiate inspiration and expiration.⁴ These cortical areas project to the motor neurons in the spinal cord via the corticospinal tracts. These corticospinal tracts are separate pathways from the reticulospinal pathways that connect the central automatic breathing centers to the motor neurons.

Automatic Breathing Controllers

Automatic breathing is controlled by a complex system that includes respiratory centers in the pons and medulla, nerve tracts in the lower brain stem, the reticulospinal pathways in the spinal cord, and the feedback mechanisms that are both chemical and mechanical in nature. There are thought to be three centers that generate the rhythm and drive to breathe, one located in the pons and two in the medulla. More detailed reviews of this topic are available.^{5,6}

Spinal Cord

The spinal cord and motor nerves conduct nerve impulses from the cortex and brain stem to the anterior horn cells of the motor neurons supplying the respiratory muscles. As noted previously, the nerve fiber tracts in the spinal cord responsible for voluntary (corticospinal tract) and automatic (reticulospinal tract) breathing are separate within the spinal cord.⁷ The fibers in both of these tracts travel through the spinal cord to synapse with the lower motor neurons.

PERIPHERAL NERVOUS SYSTEM

Lower Motor Neurons

The lower motor neuron has its cell body in the spinal cord (anterior horn cell) but exits the spinal cord to become the spinal nerve roots and the nerves that supply the respiratory muscles. When the nerves arrive at the muscle, they divide into branches known as *twigs* that, upon reaching the muscle fiber, further divide into bulbous projections called *boutons* that apply themselves to the muscle membrane at a specialized anatomic junction called the *motor end plate*. These boutons contain acetylcholine, which is the chemical transmitter that serves to excite the muscle to contract. With nerve firing, there is release of acetylcholine at

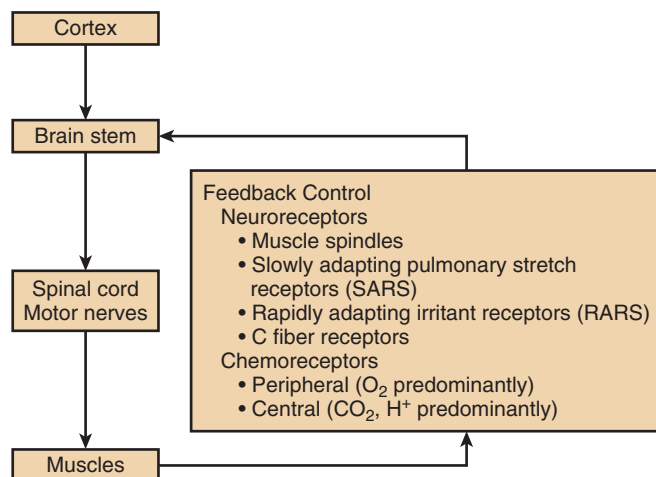

Figure 97-1 Respiratory system feedback control. Neuromechanical respiratory system shows the neuromuscular pathways and feedback control.

the motor end plate into the cleft between the nerve and the muscle. The acetylcholine binds to receptors on the muscle side of the motor end plate, which results in a *suprathreshold excitatory end plate potential* and depolarization of the muscle membrane.⁸ A muscle action potential then results in contraction of the muscle fiber.

Total Lung Capacity

Respiratory Muscles. The respiratory muscles are the mechanical effectors of the breathing system. They are often divided into three major groups: (1) the inspiratory muscles, (2) the expiratory muscles, and (3) the accessory muscles of respiration. The muscles that maintain patency of the upper airway during the respiratory cycle are sometimes also considered muscles of respiration because of their close interaction with the other respiratory muscles.

The diaphragm is the major muscle of inspiration and accounts for approximately 70% of the inhaled tidal volume in the normal individual⁹ (Fig. 97-2). Contraction of the diaphragm results in a downward piston motion of the muscle as well as outward and upward movement of the ribs through the *zone of apposition*. The innervation of the diaphragm is via the phrenic nerve that originates from cervical nerve roots 3 through 5.

The intercostal muscles are thin sheets of muscular fibers that run between the ribs in the costal spaces.¹⁰ There are two sheets of muscle fibers, the external and internal intercostals. The external intercostals function to expand the rib cage during inspiration. The internal intercostals are deeper and function to decrease rib cage size during expiration. The mechanism of action of the intercostal muscles on the ribs is shown in Figure 97-3. The orientation of the muscle fibers with respect to the ribs results in the increase or decrease in the size of the rib cage; as the muscles contract, the greater torque is applied to the point more distal from the spine. In the case of the external (inspiratory) intercostal muscles, the distal attachment is at the lower rib, so contraction tends to pull the lower rib upward, thereby expanding the chest; for the internal (expiratory) intercostal muscles, the distal attachment is at the upper rib and thus contraction of the muscle tends to pull the upper rib

Figure 97-2 Diaphragmatic positions at rest (top) and at full contraction (bottom). At functional residual capacity (top), the diaphragm lies within the chest with a zone of apposition along the chest wall. At total lung capacity (bottom), the contracted diaphragm has displaced abdominal contents and, via the increase in abdominal pressure, has expanded the chest wall outward.

Figure 97-3 Actions of the intercostal muscles on the ribs. Contraction of the external intercostals results in an upward and outward movement of the ribs during inhalation. Contraction of the internal intercostals results in a downward and inward movement of the ribs during exhalation.

down, thereby decreasing the chest. Innervation of the intercostals is via the intercostal nerves originating from the thoracic spinal nerve roots.

The abdominal muscles (rectus abdominis, internal oblique, external oblique, and transversus abdominis) serve a number of functions in respiration that mainly assist expiration but can also function in inspiration. The internal and external obliques and the transversus abdominis result in an inward movement of the abdominal wall that displaces the diaphragm upward into the thoracic cavity and assists exhalation. The rectus abdominis as well as the internal and external obliques pull the lower rib cage caudally and thereby increase pleural pressure and exhalation. The abdominal muscles also may play a minor role in inspiration¹¹; if their contraction reduces lung volume below *function residual capacity* (FRC), abdominal muscles can store elastic recoil energy in the chest wall that then assists expansion of the chest wall during the next inspiration. This “inspiratory assist” may be seen during exercise where expiration becomes active.

The accessory muscles of respiration (sternocleidomastoid, scalenes, trapezii, latissimus dorsi, platysma, and pectoralis major and minor muscles) can expand the rib cage and assist inspiration during situations of increased ventilatory demand such as during exercise or when other inspiratory muscles are impaired as in tetraplegia or chronic obstructive pulmonary disease. It is now clear that some of them function during minimal exertion and even during quiet tidal breathing.¹²

The muscles of the upper airway are also considered to be muscles of respiration because they maintain patency of the upper airway and allow air to flow into and out of the lungs without interruption.¹³ Some of these also participate in protection of the lower airway during swallowing, a key function in the defense of the respiratory system. The upper airway muscles include the abductors of the vocal cords, the palatal elevators, retractors of the tongue, and dilators of the nares. These muscles are innervated by cranial nerves V, VII, and IX–XII. The central control centers for these muscles are the same as those described previously for the more commonly considered ventilatory muscles.

CONTROLLER FEEDBACK

The respiratory control mechanisms depend on both neural and chemical receptors found in peripheral and central sites. An excellent discussion of this topic is available.¹⁴ The automatic respiratory centers in the brain stem respond to feedback from these receptors and adjust neural output to the ventilatory and upper airway muscles that expand the chest wall and maintain upper airway patency (see Fig. 97-1).

Neural receptors are present in the upper airway, respiratory muscles, lungs, and pulmonary vessels.¹⁴ Once stimulated, these receptors project signals to the central respiratory controller via the vagus nerve. The respiratory centers then adjust their output to the respiratory muscles to alter ventilation and modulate reflexes such as cough and sneeze. There are several different types of neural receptors. *Muscle spindles* and *slowly adapting pulmonary stretch receptors* predominantly respond to changes in tho-

racic cage and lung volume, respectively. As the chest wall and lung inflate, these receptors are stretched and dampen the output from the inspiratory centers in the medulla. These receptors are involved in the “Hering-Breuer” reflex in which inspiration is halted as lung volume increases.¹⁵ These are critical for initiating cough. *Rapidly adapting irritant receptors* respond to changes in lung volume, to chemical stimuli such as histamines and prostaglandins, and to noxious stimuli. *C fibers* in the airways and lung are stimulated by chemical stimuli in the local environment. The C fibers likely mediate the hyperventilation that is seen in normoxic circumstances in a number of pulmonary disorders such as asthma, pulmonary embolism, pneumonia, and pulmonary edema.

Chemical receptors or *chemoreceptors* are located both peripherally as well as in the central nervous system.¹⁴ The *peripheral chemoreceptors*, which include the carotid and aortic bodies, are the primary site for sensing low levels of *arterial oxygen pressure* (arterial PO_2) but also respond to a lesser extent to changes in *arterial carbon dioxide pressure* (arterial PCO_2) and pH. They are stimulated when the arterial PO_2 falls below 75 mm Hg as well as when the arterial PCO_2 increases and pH decreases. Whereas both receptors stimulate ventilation in hypoxia, the aortic chemoreceptors are more important in infants and the carotid receptors are more important in adults.¹⁶ Once stimulated, the carotid bodies send impulses via cranial nerve IX to the nucleus tractus solitarius where neurotransmitters are released that increase ventilation.¹⁷ Although the control of ventilation during exercise is not completely understood, the predominant stimulus for increased ventilation is thought to arise from the peripheral receptors. It is postulated that additional peripheral receptors exist that are yet to be identified because the hyperventilatory response of exercise cannot be fully accounted for by the carotid bodies.¹⁸ The *central chemoreceptors* are crucial in the adjustments of ventilation to acid-base disturbances and arterial PCO_2 . There are four groups of chemosensitive neurons in the brain stem: the locus ceruleus, the nucleus tractus solitarius, the midline raphe, and the ventrolateral quadrant of the medulla. The central chemoreceptors are responsible for most of the response to carbon dioxide. They respond to increases in arterial PCO_2 by their detection of the fall in pH of the cerebrospinal fluid associated with an increase in cerebrospinal fluid arterial PCO_2 ,³ which closely follows an increase in serum arterial PCO_2 . Of note, it appears that the parasympathetic nervous system is important in the response to cerebrospinal fluid pH changes because inhibition of acetylcholine transmission can abolish the central pH response in animals.¹⁷

DISEASES AFFECTING THE RESPIRATORY SYSTEM

The diseases of the neurorespiratory system can be organized most logically in the framework of functional anatomy. Diseases of the central nervous system known to affect the respiratory system are listed in Table 97-1 and those affecting the peripheral nervous system are listed in Table 97-2.

Table 97-1 Diseases of the Central Nervous System Associated with Respiratory Dysfunction

Cerebral Cortex	Brain Stem/Basal Ganglia	Spinal Cord
Stroke	Stroke	Trauma
Neoplasm	Neoplasm	Infarction or hemorrhage
Cerebral degeneration	Poliomyelitis	Demyelinating disease
Seizures	Central alveolar hypoventilation	Disc compression
	Progressive bulbar palsy	Syringomyelia
	Multiple system atrophy	Tumor
	Anoxic encephalopathy	Epidural abscess
	Encephalitis	
	Multiple sclerosis	
	Parkinson disease	
	Chorea	
	Dyskinesias	

Table 97-2 Diseases of the Peripheral Nervous System Associated with Respiratory Dysfunction

Motor Nerves/ Anterior Horn Cell	Neuromuscular Junction	Myopathies
Acute idiopathic demyelinating polyneuropathy (Guillain-Barré syndrome)	Myasthenia gravis	Muscular dystrophies
Motor neuron disease	Lambert-Eaton myasthenic syndrome	Myotonic dystrophy
Amyotrophic lateral sclerosis	Toxins	Poly- and dermatomyositis
Spinal muscular atrophy	Botulism	Glycogen storage diseases
Primary lateral sclerosis	Snake venoms	Pompe disease
Critical illness neuropathy	Scorpion bites	Forbes-Cori disease
Vasculitides	Shellfish	Thick filament myopathy
Toxins (e.g., lithium, arsenic, gold)	Crab poisoning	Mitochondrial myopathy
Metabolic	Drugs	Nemaline body myopathy
Diabetes	Antibiotics	Severe hypokalemia
Porphyria	Neuromuscular junction blockers	Hypophosphatemia
Uremia	Anticholinesterase inhibitors	
Diphtheria	Corticosteroids	
	Lidocaine	
	Quinidine	
	Lithium	
	Antirheumatics	

CENTRAL NERVOUS SYSTEM DISEASES

Cortical and Brain Stem Disorders

Diseases of Voluntary Breathing. The pathways that connect the voluntary respiratory centers of the cortex with spinal motor neurons (corticospinal tracts) can be affected in a number of disorders. Midpontine strokes can damage the corticospinal tracts and cause what is known as the “locked-in syndrome,”¹⁹ a syndrome with total paralysis with the exception of eye movement. Because injury to the reticulospinal tracts causes loss of volitional but not automatic breathing, the response to automatic breathing is preserved.²⁰ This syndrome is most commonly due to ischemic stroke but can be due to pontine tumor, central pontine myelinolysis, high cervical demyelination, syphilitic arteritis, and head injury. Extrapontine disorders such as parkinsonism can also affect voluntary breathing.²¹ In these disorders, patients have less ability to alter their

breathing pattern voluntarily. They also may demonstrate periodic breathing or a Cheyne-Stokes respiratory pattern.

Diseases of Automatic Breathing. Automatic breathing but not voluntary breathing is classically disrupted in central alveolar hypoventilation, otherwise known as “Ondine’s curse,”²² caused by injury to the automatic respiratory centers in the brain stem. Because automatic triggering controls breathing during sleep, individuals with central hypoventilation develop central sleep apnea. Congenital central alveolar hypoventilation is a rare genetic disorder affecting infants and children, although it has now been described in adults as well.²³ Acquired central alveolar hypoventilation can result from unilateral or bilateral medullary infarction, bulbar poliomyelitis, or bilateral cervical tractotomy performed to control chronic pain. Although disorders of the neurorespiratory system generally lead to hypoventilation and the need for ventilatory support, diseases of the automatic respiratory centers in the brain stem can also lead to hyperventilation. This may be caused by diseases such as central nervous system infection or tumor²⁴ or by stimulation of an otherwise normal autonomic respiratory center by fever, sepsis, pain, pregnancy, medications such as progesterone or salicylates, or high altitude. A variety of irregular breathing patterns have also been associated with central nervous system disease including Cheyne-Stokes respiration and ataxic breathing.²⁵

Diseases of the Spinal Cord

Spinal Cord Injury. *Spinal cord injury* (SCI) is most commonly due to traumatic injury caused by motor vehicle accidents, falls, sports accidents, and gunshot wounds. In the United States, an estimated 250,000 individuals have suffered significant SCI; the incidence is approximately 12,000 incident cases per year with 78% of the injuries seen in males (National Spinal Cord Injury Statistical Center <http://www.spinalcord.uab.edu>). Respiratory complications including atelectasis, pneumonia, and respiratory failure are the leading cause of morbidity and mortality for individuals with SCI.^{26,27} Immediately following acute SCI, a number of physiologic changes can affect the respiratory system and predispose to respiratory complications. These aberrations include (1) cough inefficiency due to expiratory muscle weakness, (2) ciliary dysfunction, (3) mucous hypersecretion possibly due to impairment of the peripheral autonomic nervous system, (4) glottic dysfunction or gastric hypomotility increasing the risk of aspiration, (5) bronchial hyperreactivity due to sympathectomy, and (6) loss of consciousness at the time of the injury, increasing the risk of aspiration.^{28,29}

Acute respiratory failure immediately after the injury may be due to direct disruption of respiratory muscle innervation (cervical cord injury), aspiration at the scene due to loss of consciousness, pulmonary edema, or other traumatic injuries to the chest or head. Many individuals with SCI are intubated at the scene of the accident or shortly thereafter. Prevention of further respiratory complications is important. Preventive measures include encouragement of deep breathing and cough, frequent changes of position, postural drainage, assisted cough (manual or mechanical), and bronchoscopy when other measures fail. Patients with SCI are at high risk for venous thromboembolism with the

Table 97-3 Respiratory Muscles and Their Innervation

Muscle Group	Spinal Cord Level	Nerve
INSPIRATORY MUSCLES		
Diaphragm	C3-5	Phrenic
Parasternal intercostals	T1-7	Intercostal
Lateral external intercostals	T1-12	Intercostal

Adductors	–	CN IX-XII

CN, cranial nerve.

greatest risk 3 days to 2 weeks after injury. Prophylaxis for deep venous thrombosis is highly recommended during the initial hospitalization.

The extent of respiratory muscle impairment following SCI mainly depends on the level and severity of the spinal injury because the function of respiratory muscles innervated below the level of the cord injury is lost. The innervation of the respiratory muscles is shown in Table 97-3. The overall pattern of pulmonary function abnormality is one of restriction.³⁰ In the first few months to a year following the initial SCI, there is a significant improvement in lung volumes and maximal inspiratory and expiratory pressures,^{31,32} possibly due to resolution of spinal cord edema and/or strengthening of the diaphragm and accessory muscles of inspiration.

In general, the higher the SCI, the more likely that ventilatory assistance will be needed.³² Treatment of ventilatory failure following SCI can be accomplished by invasive (tracheostomy) or noninvasive (mask or mouthpiece) methods.³³ Many individuals are ventilated through a tracheostomy tube for some time after their injury; however, transfer to noninvasive means can often be achieved even for those requiring full-time ventilatory support. The choice of invasive versus noninvasive ventilation is determined by the degree of local expertise with these forms of ventilation as well as by patient preference. For those with high cervical SCI (C1-2) and intact phrenic nerve function, diaphragm pacing either via a laparoscopic approach or thoracic approach is also a possibility. It should be noted that those with diaphragm pacemakers implanted still need a tracheostomy in place to avoid airway obstruction during sleep owing to the absence of the normal neurologic coordination of diaphragm contraction and upper airway dilation during inspiration. Although traumatic SCI is the major cause of spinal cord pathology, other causes include vascular accidents, demyelinating diseases (multiple sclerosis, transverse myelitis), syringomyelia, tumors, and epidural abscess (see Table 97-1).

Ventilator dependence in patients with SCI is more common with high (cervical) SCI. Because the diaphragm is the major muscle of inspiration (C3-5 spinal nerve roots), those with lesions at C3 and above invariably require ventilatory support and are at the highest risk of respiratory complications.^{27,34} Those with injuries between C3 and C5 vary in their requirements for ventilatory support. Even if they require ventilation initially, these individuals may become independent of ventilatory support eventually.^{32,35} The risk for ventilator dependence in this group of patients is greatest for those with injury close to C3 or age older than 50 years.³² Individuals with lesions below C5 almost always become independent of continuous ventilator support. In contrast to inspiratory muscle function, expiratory muscle function is impaired after all levels of cervical cord injury resulting in expiratory muscle weakness and ineffective cough. Because an effective cough depends in large part on abdominal and intercostal muscle function (spinal nerve roots T1-L1), cervical, thoracic, and even some high lumbar SCIs can impair the ability to cough and clear secretions. Therefore, measurement of cough function in these patients is very important.

Other Respiratory Effects of Spinal Cord Injury. For unknown reasons, the frequency of sleep apnea appears to be increased by as much as fourfold in patients with SCI compared to a normal population of similar age.^{36,37} A sleep study should be considered when symptoms of nocturnal hypoventilation such as morning headache, daytime hypersomnolence, or unexplained nocturnal awakenings are present or when daytime hypercarbia (arterial PCO₂ > 45 mm Hg), unexplained cor pulmonale, or *forced vital capacity* (FVC) less than 50% predicted are present.³⁸ Bronchial hyperreactivity and bronchial hypersecretion are also present in some individuals following SCI likely due to interference with normal autonomic control of the airways after injury.³⁹

PERIPHERAL NERVOUS SYSTEM DISEASES

Diseases of Motor Nerves or Anterior Horn Cells and Diseases of the Neuromuscular Junction

Disorders of the motor nerves and the *neuromuscular junction* (NMJ) can arise acutely as in acute inflammatory polyneuropathy (Guillain-Barré syndrome) or botulinum toxicity or can arise more chronically as in motor neuron disease (e.g., *amyotrophic lateral sclerosis* [ALS]) or myasthenia gravis (see Table 97-2). The level of motor nerve root involvement dictates the effects of the disorder on the respiratory system.

Acute Diseases Affecting Motor Nerves

Acute Immune-Mediated Polyneuropathy. Acute immune-mediated polyneuropathy, also referred to as Guillain-Barré syndrome, is a heterogeneous group of diseases that are now thought to be caused by antiglycolipid antibodies.⁴⁰ Acute idiopathic demyelinating polyneuropathy is the most common form, making up about 85% to 90% of cases. It is an acute progressive process characterized by symmetrical, ascending muscle weakness progressing over a 2-week period and associated with loss of deep tendon

reflexes. It is thought that an antecedent viral infection induces an immune response to viral epitopes that then cross-react with lipid components of the peripheral nerve.⁴¹ The process usually starts in the lower extremities but may start in the arms or the face, head, and neck primarily (Miller-Fisher variant).⁴²

Acute idiopathic demyelinating polyneuropathy affects the respiratory system by causing (1) weakness of the upper airway muscles, (2) weakness of the inspiratory and expiratory muscles, and (3) secondary complications such as pneumonia or pulmonary embolism.⁴³ Approximately 25% to 50% of patients develop respiratory insufficiency severe enough to necessitate intubation and mechanical ventilation.^{44,45} A number of variables used to predict impending respiratory failure and the need for mechanical ventilatory support have been used including FVC, *maximal inspiratory pressure* (MIP), maximal expiratory pressure, and nocturnal desaturation. Generally accepted guidelines for intubation and mechanical ventilation include an FVC less than 15 mL/kg, an FVC less than 1 L, a decline in FVC to 50% or less of the normal predicted value for that individual or an MIP of 30 cm H₂O or less.⁴³ FVC and MIP should be monitored frequently (multiple times per day depending on rapidity of progression). With rapidly progressive disease, the *intensive care unit* (ICU) is considered the best location for monitoring. Absolute indications for intubation include impaired consciousness, respiratory or cardiac arrest, shock, arrhythmias, blood-gas alterations, or bulbar dysfunction with confirmed aspiration.⁴³ Noninvasive ventilation is generally not an option for these individuals because they are at a high risk for aspiration because of bulbar muscle involvement. Successful extubation may be achieved once treatment such as steroids, immune globulin, and plasmapheresis is begun and respiratory muscle strength returns.⁴⁶ Until respiratory muscle strength returns, scrupulous supportive ICU care including tracheostomy for prolonged mechanical ventilation is required to prevent complications such as ventilator-associated pneumonia and sepsis.

Poliomyelitis. Poliomyelitis is a viral disease affecting the anterior horn cell and therefore motor nerve caused by a human enterovirus that caused significant epidemics with frequent respiratory complications in the United States and Western Europe during the 20th century. Owing to improved sanitation and vaccine development, polio is no longer a major public health issue in the developed world. However, in the developing world, acute infections still happen.⁴⁷

In the developed world, the major health issue arising from polio currently is the postpolio syndrome, in which new weakness develops in survivors of the polio epidemics of the mid-20th century.^{48,49} The cause of progressive neurologic deterioration in postpolio syndrome is unknown. Theories of pathogenesis suggested include (1) progressive degeneration of reinnervated motor units, (2) persistence of poliovirus in neural tissue, or (3) induction of autoimmunity with subsequent destruction of neural structures.^{50,51} The average time to onset from the time of the initial infection is 35 years but ranges from 8 to 71 years. A high percentage of polio survivors, between 20% and 60% of individuals, complain of new muscle weakness.⁵¹ Although the exact incidence of respiratory system involvement in postpolio syndrome is not known, sleep-disordered

breathing is common and noninvasive nocturnal ventilation can be highly effective.⁵² Fortunately, it appears that frank hypoventilation associated with the postpolio syndrome is unusual.⁵³

Chronic Diseases Affecting Motor Nerves

Amyotrophic Lateral Sclerosis. *Amyotrophic lateral sclerosis* (ALS) is a progressive neurodegenerative disease with no known cure. The usual clinical presentation is that of an individual with gradually progressive asymmetrical weakness associated with hyperreflexia due to upper motor nerve involvement and muscle fasciculations due to lower motor nerve involvement. Like most neurologic diseases, ALS has no direct effect on the lung; however, it significantly affects the upper airway, chest wall, and diaphragm, thereby impairing respiratory muscle function. Indeed, ALS affects all of the major muscle groups of the respiratory system including (1) upper airway muscles leading to abnormal swallowing and inadequate cough, (2) expiratory muscles leading to inadequate cough, and (3) inspiratory muscles leading to inadequate ventilation. Therefore, all patients with ALS are at significant risk for respiratory complications. Respiratory failure, the leading cause of death in this population, has been reported as the initial clinical presentation of ALS.⁵⁴ Patients may complain of dyspnea, difficulty managing secretions, or inability to cough effectively. Monitoring pulmonary function in the outpatient setting is crucial. The FVC is the most commonly used measurement and has prognostic significance.^{55,56} Attention must be given to glottic and cough function as well because aspiration and pneumonia are significant contributors to morbidity and mortality.⁵⁷ Sleep-disordered breathing is very common in ALS and *noninvasive positive-pressure ventilation* (NPPV) has been used both at night and, as the disease progresses, during the day to improve quality and duration of life.⁵⁸⁻⁶⁰ Patients often have difficulty managing secretions owing to swallowing dysfunction. Secretions can be reduced by using anticholinergic agents,⁶¹ by low-dose irradiation of salivary glands,⁶² or by injecting the glands with botulinum toxin.^{61,63} As ALS progresses, NPPV ceases to be effective and a decision needs to be made concerning the appropriateness of tracheostomy and long-term invasive ventilation. Although tracheostomy can prolong survival substantially,⁶⁴ it does not alter the progression of the disease and patients ultimately become completely paretic. Due to different cultural approaches, rates of invasive ventilation vary substantially among countries.⁶⁵

Neuromuscular Junction Diseases

Myasthenia Gravis. Myasthenia gravis is the most common disease affecting neuromuscular transmission. It is an autoimmune disease characterized by an antibody-mediated immune attack directed at acetylcholine receptors and/or receptor-associated proteins in the postsynaptic membrane of the NMJ. It causes weakness of several muscle groups including the respiratory muscles. The respiratory muscles are particularly susceptible to fatigue during the severe, potentially life-threatening, exacerbations known as *myasthenic crises*.⁶⁶ The clinical considerations during myasthenic crisis are very similar to those for acute idiopathic demyelinating polyneuropathy noted earlier and the indications for intubation are the same.⁴³ Acute treatment

of myasthenic crisis focuses on rapid therapies including intravenous immunoglobulin as well as plasmapheresis and corticosteroid therapy.^{67,68} Assiduous attention to respiratory care provides support of the patient, allowing time for therapy of the underlying myasthenia to be effective.

Myasthenia gravis can also arise as a paraneoplastic syndrome in association with thymoma. It has been estimated that approximately 15% of all patients with thymoma will exhibit myasthenia gravis. Removal of the thymoma may result in amelioration of the myasthenia symptoms. Predictors of improvement after thymectomy have been reported to be age younger than 35 years, less than 24 months from the onset of symptoms, and absence of perioperative steroid use.⁶⁹

The *Lambert-Eaton myasthenic syndrome* (LEMS) is a myasthenic syndrome associated with small cell lung cancer that can affect the respiratory muscles in a fashion similar to that of myasthenia gravis. In patients with small cell lung cancer, LEMS may be present in approximately 3% of cases.⁷⁰ However, in patients with LEMS, as many as 50% to 60% will have a tumor, almost always a small cell lung cancer. The small cell lung cancer may be occult and should be sought for up to 5 years after the diagnosis of LEMS. LEMS is thought to be due to autoantibodies directed against presynaptic voltage-gated calcium channels,⁷¹ thereby interfering with synaptic function. These voltage-gated calcium channels may be shared by the neuroendocrine cells of the small cell lung cancer, thus explaining the association of the two conditions. Although respiratory involvement is often a late finding, frank respiratory failure can be a manifestation of LEMS,⁷² and this disorder should be considered in individuals with unexplained neuromuscular weakness. Although LEMS shares a similar pathophysiologic mechanism with myasthenia gravis, the clinical presentation is different; LEMS is characterized by (1) an increase in the compound muscle action potential with repetitive nerve stimulation, a feature not seen in myasthenia, (2) more frequent presence of proximal leg weakness, which is worse in the morning, (3) greater autonomic dysfunction, and (4) frequent association with malignancy.⁷³

Botulism. Botulism is a neuroparalytic syndrome caused by a toxin produced by the gram-positive bacterium *Clostridium botulinum* that acts at the NMJ. It can be acquired by humans in one of five ways: (1) food-borne botulism, in which there is ingestion of food contaminated with preformed toxin, (2) wound botulism, in which the bacteria growing in the wound produce toxin in vivo, (3) infant botulism, in which there is ingestion of clostridial spores allowing colonization of the host's gastrointestinal tract by the bacteria and production of the toxin in vivo, (4) adult enteric infectious botulism, which is similar to infant botulism, and (5) inhalational botulism, which follows inhalation of aerosolized toxin released in an act of bioterrorism⁷⁴ (see Chapter 40).

C. botulinum produces a number of toxins that can produce paralysis by binding to synaptotagmin I and II receptors that mediate toxin entry into the nerve cell cytoplasm.⁷⁵ Once intracellular, the toxin produces irreversible disruption in stimulation-induced acetylcholine release. The botulinum toxin is one of the most potent toxins known. Recovery from the injury requires regrowth of

new synapses, a process that can take 6 months. The clinical syndrome is one of progressive paralysis with early cranial nerve involvement causing blurred vision, dysphagia, dysarthria, and facial weakness. Descending muscle weakness is the usual course and involvement of the upper airway, diaphragm, and intercostal muscles often leads to the requirement for intubation and mechanical ventilation.⁷⁶ All patients should be monitored in the ICU and intubation should be undertaken for those who cannot protect their airway or who have a vital capacity of less than 30% predicted. Botulism antitoxin (intravenous botulinum immune globulin) is available for use in the United States and is given to infants younger than 1 year of age.⁷⁷ For adults in the United States, an investigational equine serum heptavalent botulism antitoxin is available through the Centers for Disease Control and Prevention.⁷⁸ For all patients, supportive care is the mainstay of therapy, and when necessary, intubation and mechanical ventilation are critical to improved survival. Prolonged hospitalization is common.

OTHER NEUROMUSCULAR JUNCTION TOXINS. A number of other toxins can affect the NMJ. The insecticides organophosphates and carbamates are potent inhibitors of acetylcholinesterase, leading to high levels of acetylcholine in the NMJ and resulting in parasympathetic and sympathetic overstimulation, skeletal muscle paralysis, and sometimes respiratory failure.⁷⁹ Several species of tick produce toxins that can inhibit NMJ neurotransmission (tick paralysis) by inhibiting influx of sodium ions and preventing presynaptic terminal axon depolarization and the release of acetylcholine at the nerve terminal.⁸⁰ Snake venom from a number of families of snakes produces neurotoxins that can cause paralysis, respiratory failure, and death owing to inhibition of neurotransmission.⁸¹ Finally, a wide range of medications can cause NMJ blockade including D-penicillamine, aminoglycoside antibiotics, fluoroquinolone antibiotics, phenytoin and other anticonvulsants, lithium, β -blockers, glucocorticoids, and magnesium sulfate.⁸²

Diseases of the Respiratory Muscles

A large number of disorders, both acute and chronic, can directly affect the respiratory muscles (see Table 97-2). Many causes of chronic muscle disease result in respiratory muscle dysfunction including genetic muscular dystrophies, myopathies, and myotonias as well as inflammatory myopathies and those associated with systemic diseases.

Duchenne and Becker Muscular Dystrophies. Duchenne and Becker muscular dystrophies are both progressive myopathic disorders caused by mutations of the dystrophin gene on chromosome Xp21.⁸³ Dystrophins are glycoproteins that coat sarcolemmal, sarcomeric, and cytosolic muscle proteins. In Duchenne muscular dystrophy, dystrophin is absent, whereas in Becker dystrophy, a milder variant, dystrophin is reduced in quantity or quality. Both disorders are inherited as X-linked recessive traits and are characterized by progressive muscle wasting and weakness.⁸⁴ Typically, weakness of limb muscles is more severe in Duchenne muscular dystrophy. Both diseases can involve the respiratory muscles, leading to substantial morbidity and mortality. The diaphragm, however, may be less susceptible than limb muscle because of different gene

transcription patterns.⁸⁵ Duchenne dystrophy can also involve cardiac muscle.

In Duchenne muscular dystrophy, weakness of proximal muscle groups usually manifests by age 2 to 3 years, while weakness of the respiratory muscles becomes evident later in childhood.⁸⁶ In Becker muscular dystrophy, weakness manifests later in childhood and individuals can remain ambulatory often into adult life. Because limb muscles are more affected than the respiratory muscles, exercise is initially limited by limb muscle weakness rather than dyspnea due to respiratory muscle weakness. However, with time, the respiratory muscles progressively weaken and dyspnea may appear with minimal exertion or at rest. Inspiratory muscle weakness can be assessed by measuring MIP. In children unable to perform this maneuver, maximal sniff pressures may provide a useful surrogate.⁸⁷ With severe inspiratory muscle weakness (MIP < 50% predicted), lung volumes are reduced and vital capacity may decline at a rate of 6% to 11% per year. This restrictive process can be worsened by concurrent scoliosis, kyphosis, or muscle contractures. Glucocorticoids and idebenone, a quinone-like drug that may enhance energy production at the mitochondria and has antioxidant properties, have been used to slow the rate of decline of lung function.⁸⁸⁻⁹³ Therapies based on genetic manipulation such as gene transfer or exon skipping to restore the proper reading frame show promise but need further evaluation.⁹⁴⁻⁹⁶

The diagnosis is often suspected by noting an elevated serum creatine kinase. However, this finding is not specific for these disorders. Often, a muscle biopsy is obtained to distinguish muscular dystrophies from inflammatory skeletal muscle disorders and other forms of dystrophy. With muscular dystrophy, there is degeneration and regeneration of muscle fibers as well as replacement of muscle by fat and connective tissue. Immunoblots for dystrophin can aid in distinguishing Duchenne from Becker muscular dystrophy. Analysis for deletions in the dystrophin gene may be useful, but detection of point mutations of this gene may be difficult.⁹⁷ Female siblings of individuals with Duchenne or Becker muscular dystrophy should be tested to determine whether they are carriers of the disease. Carriers often have elevated creatine kinase levels.⁹⁸ It is important to identify carriers not only for genetic counseling but also because they may be at higher than average risk for development of cardiomyopathy.

The combination of a restrictive pulmonary deficit and expiratory muscle weakness impairs cough and therefore predisposes these individuals to development of respiratory complications such as atelectasis and pneumonia. Methods for preventing atelectasis and infection are discussed later in this chapter.

As the inspiratory muscles further weaken, the restrictive lung dysfunction becomes severe, with total lung capacity and vital capacity dropping to less than 60% predicted. Individuals with a vital capacity less than 30% predicted are at high risk for nocturnal hypoventilation. These individuals often experience symptoms related to nocturnal hypoventilation such as non-refreshing sleep and fatigue. Nocturnal ventilation is usually initiated if symptoms are related to nocturnal hypoventilation, right heart failure, or elevated arterial PCO₂ (>45 mm Hg) either at night or during the day. In general, daytime measures of respiratory

muscle strength or lung volumes are poor predictors of nocturnal hypoventilation and overnight oximetry or a sleep study should be considered in high-risk individuals. Noninvasive ventilation is a therapeutic intervention that typically can be delivered with a positive-pressure device using an interface such as a nasal mask, nasal-oral mask, or mouthpiece (discussed later). Although there are no randomized controlled trials in patients with muscular dystrophy, noninvasive ventilation is likely to improve quality of life, physical activity, and hemodynamics and to normalize arterial blood gases.^{99,100} Extension of noninvasive ventilation into waking hours may provide relief of dyspnea in more severely affected patients. Endurance and strength training targeting the inspiratory muscles may slow the progression of the disease in individuals with mild to moderate weakness.¹⁰¹ Individuals with Duchenne or Becker muscular dystrophy who require surgery may be at higher risk for respiratory complications.¹⁰² A consensus statement has been published addressing the respiratory and other risks of anesthesia and suggesting methods for avoiding excessive morbidity and mortality.¹⁰³

Other muscular dystrophies such as limb girdle muscular dystrophy, fascioscapulohumeral dystrophy, and myotonic dystrophy can affect the respiratory muscles but do not generally cause respiratory impairment until later in the course of the disease.

Chronic Inflammatory Myopathies. *Dermatomyositis* (DM), *polymyositis* (PM), and *inclusion body myositis* (IBM) are systemic inflammatory diseases of unknown etiology that cause profound skeletal muscle weakness.¹⁰⁴ PM and DM, with a prevalence of roughly 1 : 100,000, affect females more than males.¹⁰⁵ Both DM and PM are characterized by muscle fiber inflammation and necrosis. With DM, the inflammatory process may be due to complement-mediated microangiopathy or related to type 1 interferons. The locus of inflammation in DM is the perifascicular fibers and blood vessels. With PM, the inflammatory response is cell-mediated and involves the muscle fascicles themselves. IBM is characterized by perivascular inflammation, inflammation of the perimysium, the sheath of connective tissue surrounding groups of skeletal muscle fibers, and the presence of characteristic vacuoles. Tau protein and beta-amyloid precursor protein may contribute to muscle injury.^{106,107}

DM and PM involve proximal muscle groups, whereas IBM may involve both proximal and distal muscle groups. DM can be seen in children and adults, whereas PM and IBM are generally seen only in adults with IBM involving those older than age 50 years with a male predominance. DM may be associated with a rash or underlying carcinoma.

Inflammatory myopathies generally cause symmetrical proximal muscle weakness with insidious onset of symptoms due to slowly progressive muscle weakness. Inflammatory myopathies can also involve the diaphragm, intercostal muscles, and accessory muscles but other peripheral muscle groups are usually more severely affected than the respiratory muscles.¹⁰⁸ IBM is similar to PM except onset of symptoms is usually after age 50 years; it is more commonly seen in men than in women. Symptoms related to respiratory muscle weakness usually are not the presenting complaints. However, respiratory muscle weakness can develop in 5%

to 10% of the patients with DM and PM¹⁰⁸ and may be found in as many as 75% of individuals when respiratory muscle function is carefully evaluated.¹⁰⁹

Interstitial lung disease may develop in up to 70% of patients with DM or PM.¹¹⁰ Interstitial lung disease may be especially aggressive with the presence of antisynthetase antibodies.¹¹¹ Individuals with DM or PM should be evaluated for the presence of restrictive pulmonary disease, which may be due to respiratory muscle weakness as well as underlying interstitial lung disease. If respiratory muscle weakness is pronounced (MIP < 30% of predicted), ventilatory failure may ensue.¹⁰⁸ Respiratory muscle weakness can also impair cough, which, in concert with esophageal dysfunction and lymphopenia, can predispose these patients to pneumonia.

Diagnostic workup includes measuring muscle enzymes and autoantibodies, magnetic resonance imaging, and muscle biopsy. Muscle enzymes (creatine kinase, aldolase, and lactate dehydrogenase) can be elevated in all inflammatory myopathies but more so in DM and PM than in IBM. Serologic markers that are specific for DM and PM include autoantibodies such as anti-Jo-1; antibodies to signal recognition particle (anti-SRP antibodies); and antibodies to Mi-2, a nuclear helicase.^{112,113} Type 1 interferon-inducible transcripts can be detected in blood in DM and PM and may play a pathogenic role.¹¹⁴ Magnetic resonance imaging provides a broad sampling of muscle and is helpful in distinguishing between PM and IBM. With IBM, abnormal changes can be seen throughout the muscle; whereas changes are only noted along fascial planes in PM.¹¹⁵ The presence of typical inclusion bodies on muscle biopsy is diagnostic of IBM.

Metabolic Myopathies

Glycogen Storage Disease. A number of enzyme deficiencies can lead to disordered glycogen metabolism, resulting in accumulation of glycogen in tissue including skeletal and cardiac muscle. The glycogen storage diseases that are most likely to affect the respiratory system are acid maltase deficiency (type II—Pompe disease) and debranching enzyme deficiency (type III—Forbes-Cori disease). These disorders usually present in childhood, but some, such as Pompe disease, have separate adult-onset forms. McArdle disease (type V) results from myophosphorylase deficiency and can lead to exercise intolerance.¹¹⁶ In general, glycogen storage disorders are inherited as autosomal recessive conditions.

Acid Maltase Deficiency. Acid maltase deficiency, also known as glycogen storage disease type II or Pompe disease, is due to the deficiency of acid α -glucosidase, an enzyme responsible for the degradation of glycogen polymers to glucose. Deficiency of this enzyme allows accumulation of glycogen within cardiac and skeletal muscle lysosomes, resulting in myopathy. Although typically involving infants, this disease can manifest in adulthood.¹¹⁷ Complete enzyme deficiency results in cardiorespiratory failure and death, usually in the first year of life.¹¹⁸ When the onset of weakness begins after age 1 year, the disease is less severe and does not involve the heart. Initially, subjects develop symptoms related to muscle weakness. Those with a later onset of symptoms have a better prognosis. With diaphragm

involvement, there may be restrictive ventilatory limitation, intolerance of the supine position, and in most severe cases, respiratory failure.¹¹⁹ Results from trials of enzyme replacement therapy with recombinant acid α -glucosidase are promising, showing stabilization of pulmonary function^{120,121} and increased survival.¹²²

Other Metabolic Myopathies. Myopathies can be caused by defects of lipid metabolism (carnitine palmitoyl transferase deficiency) or disorders involving the mitochondria directly. Disorders of lipid metabolism may be caused by an abnormal carnitine transporter protein (“primary” carnitine deficiency) or a deficiency of carnitine secondary to other metabolic diseases.¹²³ These disorders usually do not cause respiratory disability but involve other skeletal muscle groups (arms and legs) and may involve cardiac muscle.

Mitochondrial disorders include those due to deficiencies of enzymes in the mitochondrial respiratory chain complexes and to defects of phosphorylation-respiration coupling. Disorders of mitochondrial metabolism involving complexes I, II, III, IV, and V cause multiple respiratory chain defects¹²⁴ and alter the kinetics of oxygen metabolism during exercise.¹²⁵ The main consequences of mitochondrial myopathy are muscle weakness, muscle wasting, and exercise intolerance. Dyspnea that accompanies exercise may be due to an exaggerated ventilatory response to metabolic demands.¹²⁵ Individuals may exhibit external ophthalmoplegia, ptosis, and hypertrophic or dilated cardiomyopathy. Occasionally, mitochondrial myopathies cause significant respiratory muscle weakness resulting in nocturnal hypoventilation and the need for assisted ventilation. Treatments that focus on bypassing the defective mitochondria include dietary supplements based on dietary substances involved in adenosine triphosphate production such as creatine.¹²⁶

SPECIAL TOPICS

NEUROMUSCULAR DISEASE RELATED TO CRITICAL ILLNESS

Neuromuscular weakness is a very common finding in patients who are in the ICU. Neuromuscular weakness develops in more than 25% of patients who are ventilated in the ICU for more than 7 days.¹²⁷ Potential causes of weakness in this context include Guillain-Barré syndrome, rhabdomyolysis, cachectic myopathy, ventilator-induced diaphragm dysfunction, and critical illness neuropathy and myopathy.

The combination of critical illness neuropathy and myopathy is now often referred to as “ICU-related weakness” or critical illness polyneuromyopathy. The incidence of critical illness polyneuromyopathy is high, with prospective studies estimating risk of 33% to 82%.¹²⁸⁻¹³⁰ Patients with sepsis, multiorgan failure, systemic inflammatory response syndrome,¹³¹ and hyperglycemia¹²⁹ are at a higher risk for this complication.¹³² Other factors that are thought to contribute to this disorder include treatment with steroids¹²⁷ or neuromuscular blocking agents,¹³³ total parenteral nutrition, aminoglycoside use, catecholamines, hyperosmolality,

female gender, longer duration of multiorgan failure, greater illness severity, and renal failure.¹³⁴

The pathophysiologic mechanisms leading to critical illness polyneuromyopathy are not well understood. However, the pathology of the myopathy has been well described and includes two major patterns of disease: (1) myocyte atrophy with thick filament (myosin) destruction¹³⁵ and (2) widespread myocyte necrosis with intracellular vacuolization and phagocytosis of muscle fibers.¹³⁶ The neuropathic changes described by electrophysiologic testing with nerve conduction studies reveal reduced motor and often sensory nerve action potentials and muscle fibrillation suggestive of denervation.¹³⁷

Critical illness polyneuromyopathy should be distinguished from other neuromuscular diseases. Compared with demyelinating diseases such as Guillain-Barré syndrome, critical illness polyneuromyopathy has normal nerve conduction velocity; compared with rhabdomyolysis, critical illness polyneuromyopathy will have a normal creatine phosphokinase, lack of muscle tenderness, and minimal electromyographic changes; and compared with cachectic myopathy, critical illness polyneuromyopathy is not usually associated with severe malnutrition.¹³⁸

The only intervention thus far shown to reduce the incidence of ICU-acquired neuromuscular disorders is intensive insulin therapy. In one randomized, controlled study, the use of insulin to maintain serum glucose at 80 to 110 mg/dL, compared with a conventional range of 180 to 200 mg/dL, reduced critical illness polyneuromyopathy in patients in the ICU for at least 1 week by 44%.¹³⁹

Ventilator-induced diaphragm dysfunction is another important cause of respiratory muscle weakness in the ICU and is associated with atrophy of both fast and slow myofibers.^{140,141} It can begin after only 24 to 36 hours of mechanical ventilation. Diaphragm ultrasound may provide a noninvasive means of assessing the function of the diaphragm in ventilated patients.¹⁴²

DISEASES AFFECTING DIAPHRAGM FUNCTION

The diaphragm, the major muscle of inspiration, is a dome-shaped structure that separates the thorax from the abdomen and is composed of two muscular leaflets attached to a central tendon (see Fig. 97-2). The diaphragm inserts into the bony rib cage along the inner surface of the lower six ribs and costal cartilages anterolaterally and the upper three lumbar vertebral bodies posteriorly. It separates the thorax from the abdomen and, when it contracts, increases the volume of the thorax and inflates the lung by decreasing intrapleural pressure. The diaphragm increases thoracic size in two main ways: by the descent of the diaphragm in a piston-like fashion and by the expansion of the rib cage via an increase in abdominal pressure. It is innervated by the phrenic nerve which arises from the C3 to C5. Diaphragm weakness or paralysis can involve either one of the diaphragm leaflets (unilateral) or both (bilateral).

Unilateral Diaphragm Paralysis

Unilateral diaphragm paralysis is more common than bilateral diaphragm paralysis. The list of potential causes is similar (Table 97-4). The most frequent causes of unilateral paralysis include phrenic nerve injury related to cardiac or

Table 97.4 Causes of Diaphragm Weakness and Paralysis

Neuropathic Causes	Myopathic Causes
Trauma Cardiac surgery with cold cardioplegia Blunt trauma Spinal cord injury Radiation injury Cervical manipulation Scalene and brachial nerve block	Muscular Dystrophies Limb-Girdle Duchenne and Becker
Tumor Compression Lung cancer Metastatic mediastinal tumor	Metabolic Myopathies Hyper or hypothyroidism Acid maltase deficiency
Metabolic Diabetes Vitamin deficiency (B6, B12, folate) Hypothyroidism	Rheumatologic Systemic lupus erythematosus Dermatomyositis Mixed connective disease
Inflammatory Neuritis Idiopathic (neuralgic amyotrophy, Parsonage-Turner) Mononeuritis multiplex Vasculitis Paraneoplastic	Miscellaneous Amyloidosis Malnutrition Idiopathic
Miscellaneous Cervical spondylosis Poliomyelitis Amyotrophic lateral sclerosis	

thoracic surgery, herpes zoster, cervical spinal disease, or invasive or compressive tumors.¹⁴³ With unilateral diaphragm paralysis, patients may be asymptomatic at rest but have dyspnea with exertion.¹⁴⁴ Orthopnea may be present but is not as common or severe as in bilateral paralysis. When dyspnea is present in patients with unilateral paralysis, co-morbid conditions such as obesity and underlying heart or lung disease may be present and other disorders that cause muscle weakness should also be evaluated.

The diagnosis is often suggested by an elevated hemidiaphragm on chest radiograph and confirmed with a fluoroscopic sniff test or by diaphragm ultrasonography.¹⁴⁵ In this test, an upward or “paradoxical” movement of the paralyzed hemidiaphragm is seen during a vigorous sniff maneuver and can be visualized by fluoroscopy or ultrasound imaging of the diaphragm dome (see Video 18-1). The paradoxical motion is due to the passive movement of a paralyzed hemidiaphragm in response to the increase in abdominal pressure (and decrease in pleural pressure) created by the contraction of the normal hemidiaphragm. Thus, the unilateral hemidiaphragmatic paralysis can be recognized readily by the different function of the two hemidiaphragms. Ultrasonographic imaging of the diaphragm in the zone of apposition provides an alternate means of diagnosing chronic unilateral diaphragm paralysis by showing a thin diaphragm that fails to thicken with inspiration (Video 97-1).¹⁴⁶ There is no specific treatment for this disorder, but recovery following the initial injury is occasionally seen. When disabling symptoms are present and there is significant elevation of the hemidiaphragm on chest radiography, surgical plication of the paralyzed hemidiaphragm to minimize its paradoxical motion has had some success in improving vital capacity and forced expiratory volume in 1 second, especially in the supine position, and in reducing dyspnea.^{147,148}

Bilateral Diaphragm Paralysis

Bilateral diaphragm paralysis is most often seen in the setting of a disease producing severe generalized muscle weakness. The most common causes are diffuse muscle diseases or motor neuron disease such as ALS. However, bilateral paralysis may develop with a myriad of disorders that involve the cervical spinal cord, phrenic nerve, or NMJ. Examples include neuralgic amyotrophy (Parsonage-Turner Syndrome) or complications following cardiac, thoracic, or neck surgery.¹⁴⁹

Patients with bilateral paralysis primarily complain of dyspnea,¹⁵⁰ either at rest, with activity, or especially when supine. Orthopnea is very common and patients may need to use a recliner to sleep.¹⁵¹ In addition, they often complain of dyspnea during activities that require bending or lifting. Dyspnea on immersion in water also has been described.¹⁵² These symptoms are related to increases in abdominal pressure and cranial displacement of the diaphragm in either the supine position or when bending. Because sleep-disordered breathing with hypoventilation and hypoxemia is common,^{153,154} these individuals generally respond well to NPPV.¹⁵⁵

Bilateral diaphragmatic paralysis can be difficult to diagnose. It may be suspected by observing paradoxical rib cage and abdomen motion during inspiration, especially in the supine patient. Pulmonary function tests show moderate restriction with the vital capacity decreasing by more than 30% when supine. Since there is no normal hemidiaphragm to use for comparison with an abnormal one, chest radiography and sniff testing can yield false-negative and false-positive results. Two-dimensional echocardiography of the movement of the diaphragm dome shares the same limitations as fluoroscopy.¹⁵⁶ Phrenic nerve conduction studies can be useful in diagnosing a neuropathic cause of diaphragmatic paralysis but can have technical limitations.¹⁵⁷ Measures of maximal inspiratory and expiratory pressures will be reduced but these tests are not specific for diaphragm dysfunction. The “gold standard” diagnostic test is measuring transdiaphragmatic pressure using thin balloon-tipped polyethylene catheters placed in the esophagus and stomach (Fig. 97-4A) and showing a lack of ability to generate a transdiaphragmatic pressure¹⁵⁸ (see Fig. 97-4B). Ultrasound of the diaphragm muscle in the zone of apposition is less invasive than measures of transdiaphragmatic pressure and is diagnostic of bilateral diaphragm paralysis when no diaphragmatic thickening is seen on either side with inspiration.¹⁵⁹

Bilateral diaphragm paralysis is rarely reversible unless the underlying disease is treatable. Spontaneous recovery, however, has been noted in more than 50% of individuals with idiopathic unilateral diaphragmatic paralysis or paralysis due to neuralgic amyotrophy (brachial plexus neuritis) with the recovery taking an average of 15 months from the onset of symptoms.¹⁵⁷ Ultrasonography has been used to follow recovery from bilateral and unilateral paralysis.¹⁶⁰ Phrenic nerve pacing can be considered but requires intact phrenic nerves and normal diaphragmatic motor function and is thus not applicable in most cases of diaphragm paralysis. Phrenic nerve pacing has been used in patients with cervical cord injuries above C-3. Direct diaphragmatic pacing involves the implantation of electrodes in the

Figure 97-4 Transdiaphragmatic pressure testing for diaphragmatic function. **A**, Apparatus used to measure transdiaphragmatic pressure. Esophageal and gastric balloons placed through the nose into the esophagus and stomach, respectively, allow measurement of the pressures above and below the diaphragm simultaneously. **B**, *Top*, Normal esophageal (Pes) and gastric (Pga) pressure tracings. Note Pes becomes more negative and Pga more positive during normal inspiration owing to the action of the diaphragm. *Bottom*, Diaphragmatic paralysis where Pes and Pga deflect in the same direction showing no muscular activity of the diaphragm.

diaphragm. Identification of the entrance points of the phrenic nerve into the diaphragm is a prerequisite for direct pacing because uniform diaphragm activation requires placing the intramuscular electrodes in these locations. Direct pacing has been used in patients with high spinal cord injury and in patients with ALS with limited success in extending time free of ventilator support.¹⁶⁰ As mentioned previously, in unilateral diaphragm paralysis, hemidiaphragm plication has been used to shorten the paralyzed hemidiaphragm and allow the unaffected hemidiaphragm to contract more effectively. Plication is not indicated in patients with bilateral diaphragm paralysis because one of the compensatory mechanisms used by these individuals to breathe requires the transmission of low subdiaphragmatic pressure across a flaccid diaphragm to the pleural space.

APPROACH TO RESPIRATORY EVALUATION AND MANAGEMENT OF THE INDIVIDUAL WITH NEUROMUSCULAR DISEASE

Although each neuromuscular disease has a different etiology and natural history as well as potential treatment, the respiratory effects of neuromuscular diseases can be approached in a systematic way that can be applied to any neuromuscular diagnosis. This approach uses the fact that the three major muscle groups involved in maintaining ventilation and protecting the airway and lungs are (1) the inspiratory muscles responsible predominantly for ventilation, (2) the expiratory muscles responsible predominantly for cough, and (3) the upper airway muscles responsible for cough, swallowing, and airway protection (Fig. 97-5). For the patient with neuromuscular disease, cough function and airway protection from an intact swallowing mechanism are as important as maintenance of ventilation.^{161,162} For patients with Duchenne muscular dystrophy, a consensus committee of the American Thoracic Society¹⁶² has recommended that clinic visits should include evaluation of each of the three areas by eliciting appropriate history, physical examination, and laboratory testing.

Inspiratory function can be tested by measurement of FVC, MIP, and carbon dioxide levels. Carbon dioxide can be measured as arterial PCO₂, the traditional measure of adequate ventilation, or as exhaled or end-tidal carbon dioxide, transcutaneous carbon dioxide, or capillary PCO₂. Arterial blood gas sampling is the most accurate means of assessing alveolar ventilation but can be uncomfortable for the patient. End tidal carbon dioxide measurement in patients without intrinsic lung disease is an easy and accurate method of estimating arterial PCO₂.¹⁶³ Transcutaneous carbon dioxide has been successfully measured in children and improving technology may allow more widespread use.¹⁶⁴

Hypoventilation usually manifests itself with symptoms associated with sleep fragmentation. Symptoms consistent with sleep-disordered breathing include more frequent nocturnal awakenings, nocturia, vivid nightmares, night sweats, daytime hypersomnolence, morning headaches, nausea, depression, decreased concentration, and diminished daytime performance. Polysomnography can be used

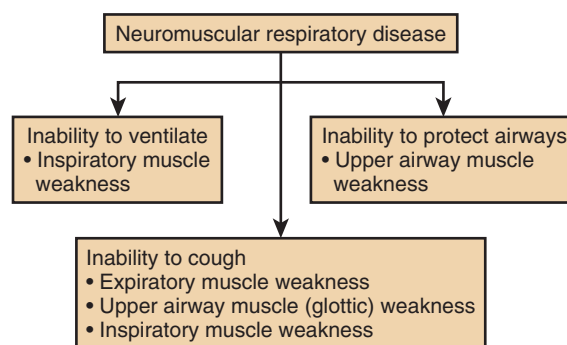

Figure 97-5 Clinical effects of weakness or dysfunction of inspiratory, expiratory, and upper airway muscles. Neuromuscular conditions lead to respiratory disease mainly via inability to ventilate, to cough, or to protect the upper airway from aspiration.

to evaluate sleep in patients with neuromuscular disease, but an overnight stay in a sleep laboratory may be especially difficult for such individuals if they require a personal care attendant, position changes, or help with toileting. Thus, ensuring a high pretest probability before ordering a sleep study is important. Baseline values of awake arterial PCO₂ of 45 or greater or base excess of 4 mEq or greater may correlate with sleep hypoventilation.¹⁶⁵ An unattended sleep study in the home¹⁶⁶ or overnight oximetry and end tidal carbon dioxide monitoring¹⁶² may substitute for a full laboratory polysomnogram; however, the sensitivity and specificity of these portable tests remains to be determined in this population.¹⁶⁶ These studies may serve to screen for those who will benefit from a full polysomnographic study in a sleep laboratory.

Cough insufficiency may be suspected if the patient describes an inability to bring secretions to the mouth for expectoration or if there is a history of frequent respiratory tract infections. Cough function is best assessed by measuring *peak cough flow* (PCF) rate. This can be easily measured with an asthma peak flowmeter connected to a face mask or mouthpiece (Fig. 97-6). Normal values range from 360 to 960 L/min¹⁶⁷; a value below 160 L/min may place individuals at high risk for cough insufficiency and ventilator dependence.¹⁶¹ During a respiratory tract infection, PCF may drop substantially and a PCF below 270 L/min during a healthy period can drop below 160 L/min during infection. Cough assistance is suggested for those with a PCF below 160 L/min.

Patients with neuromuscular diseases such as ALS frequently develop bulbar muscle dysfunction due to motor neuron involvement in the brain stem. Dysfunction of the lips, tongue, and pharyngeal and laryngeal muscles can result in an increased risk of aspiration as well as difficulty with generating adequate glottic closure for effective cough function. Swallowing may be impaired and ingesting adequate nutrition can be challenging for the patient. Choking is common and may even be triggered by aspiration of saliva. Malnutrition or rapid weight loss should signal the clinician to assess the swallowing mechanism.¹⁶⁸ Swallowing may be tested by barium swallow or direct visualization of swallowing endoscopically.¹⁶⁹⁻¹⁷¹ Referral to a speech and swallowing clinic can be very helpful in diagnosing swallowing and airway protection problems as well as instructing patients and their families in ways to reduce the risk of aspiration.

VENTILATORY SUPPORT

Ventilatory support for patients with neuromuscular disease has been available for more than 60 years¹⁷² (Table 97-5). Some of the first ventilators were known as body ventilators and included devices such as the iron lung, rocking bed, and pneumobelt.¹⁷³ With the advent of positive pressure via either invasive (tracheostomy) or noninvasive (face mask) ventilation, these body ventilators are used only very rarely, generally for patients who have already been using them for years.

Invasive positive-pressure ventilation using an indwelling tracheostomy has been successfully employed in neuromuscular disease. Benefits of this type of ventilator support include complete control of machine-delivered tidal volume and ease of access to the central airways for suctioning of secretions. In addition, if there is an acute decline in respiratory function, the same method of ventilation can be used for ventilatory support. The development of convenient, portable, positive-pressure generators has made this form of ventilation practical even in the home environment.¹⁷⁴ Invasive positive pressure should be considered in those with (1) coexisting lung disease, (2) copious secretions, (3) poor oropharyngeal muscle strength associated with ineffective clearing of secretions, (4) uncontrolled seizure dis-

orders that can cause upper airway obstruction, (5) a preference for invasive rather than noninvasive methods, (6) orthopedic or other conditions that interfere with placement of noninvasive devices, and (7) limited access to individuals with expertise in noninvasive techniques.

Unfortunately, invasive long-term positive-pressure ventilation via a tracheostomy has been associated with several complications such as damage to the trachea from the indwelling tracheostomy tube leading to tracheal necrosis, stenosis, hemorrhage, or tracheoesophageal fistulas.¹⁷⁵ However, the development of low-pressure, high-volume cuffed plastic tracheostomy tubes has lowered the incidence of these complications. Tracheostomy tubes can interfere with the normal swallowing mechanism and predispose patients to swallowing problems and food aspiration; they can also increase the risk of airway colonization with bacteria and lower respiratory tract infection. The use of a tracheostomy tube requires supplemental humidification, an additional daily respiratory care task. Finally, social interactions and psychological well-being may be impaired by the inability to speak. However, a number of devices and techniques have been designed to allow speech and communication while a patient has a tracheostomy and is mechanically ventilated. These include one-way valves that allow gas to pass through the vocal cords during exhalation (Passy-Muir valve, Irvine, CA) or channels to direct compressed air through the vocal cords (“Trach Talk” tracheostomy tube). Unfortunately, not all individuals can use these devices.

NPPV is becoming the preferred method for treatment of patients with neuromuscular respiratory disease.¹⁷⁶ The noninvasive delivery of positive-pressure ventilation was first used during the polio epidemics of the 1950s to allow patients time outside the iron lung. Since the 1980s, there have been considerable refinements in the application of this technique. There are currently three ways in which NPPV may be delivered: (1) via full face mask, (2) via nasal mask, or (3) via mouthpiece with or without a lip seal (Fig. 97-7). Occasionally, more than one method may be used in the same patient, for instance, a mouthpiece may be used during the day and a nasal mask used at night.

The mouthpiece was the first interface to be used with a positive-pressure ventilator. Patients hold the mouthpiece devices between their teeth and often are able to use them while sleeping, especially when lip seal devices are added.¹⁷⁷ Since the late 1990s, nasal interfaces have been developed and used successfully. Initially, nasal masks were designed to deliver continuous positive airway pressure for the

Figure 97-7 Different means of delivering noninvasive positive-pressure ventilation. **A**, Full mask. **B**, Nasal mask. **C**, Mouthpiece.

treatment of patients with sleep apnea.¹⁷⁸ Currently, they are also used to deliver intermittent positive pressure to patients with neuromuscular disease. Tidal volume is most effectively delivered when there are no leaks around the nasal mask or through the mouth. Patients who experience air leaks may develop oxyhemoglobin desaturation, elevation of arterial PCO_2 , and associated symptoms. In this situation, the use of a full face mask interface may be more appropriate. Using custom-designed appliances also can eliminate leaks via the mouth and may be more comfortable for some patients. Pressure-cycled rather than volume-cycled devices are generally used for mask ventilation. With these machines, positive pressure can be delivered at two levels, a higher level during inspiration and a lower level during expiration (bilevel support, BiPAP). The positive-pressure gradient during inspiration results in delivery of a tidal volume to the patient. Exhalation is passive and is terminated when the airway pressure returns to the lower expiratory level. Maintenance of a positive expiratory pressure is important for two reasons. First, the gas flow needed to maintain end-expiratory positive airway pressure flushes the ventilator tubing of exhaled carbon dioxide and prevents rebreathing.¹⁷⁹ Second, because the expiratory pressure is positive and greater than atmospheric, the end-expiratory lung volume is increased, which may be associated with less atelectasis and fewer areas of low ventilation-perfusion or shunt than seen with low end-expiratory lung volumes.

DATA SUPPORTING NONINVASIVE POSITIVE-PRESSURE VENTILATION IN NEUROMUSCULAR DISEASE

Nocturnal Ventilatory Support

The use of nocturnal ventilation in patients with neuromuscular disease with sleep-disordered breathing has been shown to have a number of benefits, including (1) reduced arterial PCO_2 and increased arterial PO_2 on and off the ventilator, (2) decreased symptoms of sleep-disordered breathing such as morning headache, nocturnal awakenings,

vivid nightmares, and night sweats, (3) improved quality of life, and (4) reduced morbidity and most likely reduced mortality. Nocturnal ventilation has become widely accepted, providing ventilatory assistance for patients while sleeping and allowing them to breathe on their own during the day. In one early study of patients with late-stage Duchenne muscular dystrophy who had symptoms of ventilatory failure and arterial PCO_2 of 60 mm Hg or greater, nocturnal negative-pressure ventilation using cuirass or tank ventilators significantly improved daytime arterial PCO_2 values (60.8 mm Hg before treatment to 45.5 mm Hg after treatment) and arterial PO_2 values (59.3 mm Hg before treatment and 74.6 mm Hg after treatment).¹⁸⁰ Since that 1981 study, a number of studies have been published using nocturnal ventilation that have supported these findings and, 20 years after, an excellent review of these data is available.¹⁸¹

The mechanism by which nocturnal ventilation improves daytime symptoms and arterial blood gases in patients with neuromuscular disease is not entirely clear. A number of explanations have been suggested including (1) resting of chronically fatigued respiratory muscles, (2) reversal of mechanical problems associated with neuromuscular disease such as reduced chest wall and lung compliance, and (3) a resetting of the central respiratory control centers with an increase in chemosensitivity to arterial PCO_2 during the daytime, thus maintaining blood gas homeostasis.¹⁸²⁻¹⁸⁴ In addition to improvement in arterial blood gases, other measures of physiologic function have been shown to improve with intermittent ventilation; for example, nocturnal ventilation can increase vital capacity, improve right heart function, and reduce erythrocytosis.¹⁸⁵

For ethical reasons, the effects of mechanical ventilation on survival generally have not been studied in a randomized controlled fashion in patients with neuromuscular disease. In most progressive neuromuscular diseases, once an elevation in arterial PCO_2 and a decrease in arterial PO_2 are noted, cor pulmonale and death are inevitable within a short period of time. It is therefore generally accepted that mechanical ventilation in the home leads to improved survival in most patients.

Full-time Ventilatory Support

For those who require full-time ventilatory support, it is possible to provide NPPV for 24 hours per day.¹⁸⁶⁻¹⁸⁸ As with nocturnal NPPV for neuromuscular disease, there have been no randomized controlled trials of continuous ventilation. In one cohort study, 24 patients with Duchenne muscular dystrophy using NPPV were compared with 22 patients who received positive-pressure ventilation by tracheostomy.¹⁸⁹ The individuals who used NPPV had significantly fewer hospitalizations and hospital days per year. In another retrospective study by the same group, patients with Duchenne muscular dystrophy using a protocol consisting of mouthpiece positive-pressure ventilation and breath stacking plus mechanical insufflation-exsufflation to assist cough (see [Cough Support](#)) had significantly less mortality (3 of 34 patients) than a group that did not have access to the protocol and either received tracheostomy or used NPPV on a near-continuous basis (27 of 31 patients).¹⁹⁰ Further studies of continuous NPPV are needed to assess whether this treatment is truly better than tracheostomy ventilation in a community setting. A consensus statement of the American Thoracic Society on the respiratory care of patients with Duchenne muscular dystrophy has suggested that NPPV be considered when expertise is available for initiation of appropriate protocols.¹⁹¹

COUGH SUPPORT

Therapeutic interventions aimed at improving cough and airway clearance are equally if not more important than ventilatory support because pneumonia is one of the leading causes of morbidity and mortality in patients with neuromuscular respiratory disease.^{162,176} Normally, the cough reflex is initiated by stimulation of cough receptors in the airways that activate brain stem centers that initiate inhalation, glottic closure, and forceful contraction of expiratory muscles during which intrathoracic air is compressed

under high pressures.¹⁶⁷ The glottis then rapidly opens allowing an explosive release of air from the airways through the vocal cords. The high velocity air flow shears secretions away from the airway walls and propels them out of the lung. Adequate cough is essential for airway hygiene. Fortunately, there are a number of ways that an impaired cough can be augmented and pulmonary hygiene maintained without the use of a tracheostomy.

Manually assisted cough is a method of applying a rapid positive pressure to the abdomen. The increase in abdominal pressure is transmitted to the thorax and induces expiratory flow, leading to airway clearance and enhanced cough expiratory flow rates. A number of techniques are available for an attendant to apply rapid abdominal thrusts, resulting in effective clearance of secretions.¹⁹² Increasing the volume of air in the respiratory system prior to the assisted cough increases the volume available for exhalation, optimizes the length-tension relationship of the expiratory muscles to increase potential intrathoracic pressure generation, and increases the inward elastic recoil pressure of the respiratory system, which can further increase the expiratory pressures. This maximal achievable inspired volume has been labeled the maximal insufflation capacity.¹⁹³ Inspired lung volume can be increased by patients using breath stacking or glossopharyngeal (“frog breathing”) techniques¹⁹⁴ or by use of a resuscitator bag and mouthpiece ([Fig. 97-8A](#)). Breath stacking involves taking multiple breaths to increase lung volumes above the single breath volume, holding each successive breath in the lungs using the glottis. Glossopharyngeal breathing is a form of respiration that involves forcing air into the trachea using the tongue and pharyngeal muscles.¹⁹⁴

Increasing the lung volume to the greatest possible volume, known as lung volume recruitment, by using breath stacking or a mechanical device may help both with cough function as well as maintaining lung compliance and forced vital capacity in progressive neuromuscular disease.^{195,196} A very effective secretion management device,

Figure 97-8 Methods to assist cough. **A**, Resuscitator bag used to “stack breaths” to increase lung volume and thereby increase cough flow. **B**, Mechanical insufflator-exsufflator being used to assist in secretion removal.

available for more than 50 years but only recently used to any great extent, is the mechanical insufflator-exsufflator or CoughAssist (In-exsufflator, JH Emerson Co.) (see Fig. 97-8B). This device consists of an electric motor that can generate positive and negative pressures of up to 50 cm H₂O to insufflate and then rapidly exsufflate the lung. The pressure is applied to the patient's airway via a face mask or mouthpiece; first, a positive pressure of 30 to 50 cm H₂O is applied over a 1- to 3-second period followed immediately by a negative pressure of between 30 and 50 cm H₂O for a short duration. By simulating a cough, this technique moves secretions out of the airway noninvasively without violating airway integrity (Video 97-2).¹⁹⁷ Other noninvasive mechanical aids include devices that oscillate the chest wall or airway directly.¹⁹⁸ These have not been well studied in neuromuscular disease patients without tracheostomy and their role in support of secretion management of these disorders is unclear.

The decision to initiate cough assistance is determined by measurement of PCF. Normal values for PCF range from 360 to 960 L/min. It is recommended that one or more of the previously discussed techniques should be made available to the patient when values of PCF fall below 270 L/min while the patient is well, because this correlates with a value of less than 160 L/min when the patient develops a respiratory tract infection.¹⁶¹ This drop in cough function with respiratory illness may be due to increased muscle weakness or to the effects of the secretions themselves in reducing expiratory flow.

Besides problems with cough, patients with neuromuscular disease often have problems with swallowing and airway protection. However, treatments for swallowing muscle dysfunction are limited. The risk of aspiration and development of pneumonia in patients with ALS is due primarily to problems with upper airway function and cough. Pharyngeal and laryngeal muscle dysfunction can lead directly to aspiration of oral contents into the lungs. Other than surgical diversion of the airway,¹⁹⁹ no treatment directly aimed at laryngeal and glottic function is available. When patients develop significant dysphagia and aspiration of solids or liquids, many experts recommend placement of a percutaneous endoscopic gastrostomy tube.^{200,201}

Key Points

- Respiratory failure is a leading cause of morbidity and mortality in individuals with neuromuscular disease.
- Spinal cord injury, a common traumatic injury worldwide, impairs respiratory function depending on the level of spinal injury.
- Acute immune-mediated polyneuropathy (acute idiopathic demyelinating polyneuropathy or Guillain-Barré syndrome) is an ascending paralytic disease thought to be caused by antiglycolipid antibodies. Intubation can be life-saving and should be considered when the FVC is 15 mL/kg or less, the FVC is 1 L or less, or the MIP is 30 cm H₂O or less, or there is a lack of upper airway protection.
- Diaphragm paralysis can be unilateral or bilateral: unilateral disease is most commonly due to injury to the phrenic nerve whereas bilateral disease is most

commonly due to diffuse muscle or motor neuron disease.

- Respiratory assessment of the individual with neuromuscular respiratory impairment should include evaluation of muscle groups responsible for inspiration, expiration and cough, and airway protection.
- Either nocturnal or full-time noninvasive ventilation is now commonly used in chronic neuromuscular respiratory disease and likely prolongs survival.
- Neuromuscular weakness arises commonly in the ICU and results in increased mortality and hospital length of stay.
- Cough can be aided noninvasively by manual or motorized means; cough support should be considered when the peak cough flow rate is less than 270 L/min in a patient without respiratory tract infection and definitely when the peak cough flow rate is less than 160 L/min.

INTRODUCTION

Disorders of the soft tissue and bony structures of the chest wall generally cause restrictive dysfunction by limiting motion or causing disordered movement of the chest wall. Kyphoscoliosis and ankylosing spondylitis are disorders that involve the spine and its articulations, pectus excavatum involves the sternum, flail chest affects the ribs, and obesity adds to the soft tissues of the rib cage and abdomen. Kyphoscoliosis has the most severe impact on respiratory function and pectus excavatum the least. Alterations in respiratory mechanics produced by these disorders are discussed in concert with the most recent developments in diagnosis and treatment. Neuromuscular diseases that affect the chest wall are reviewed in Chapter 97.

KYPHOSCOLIOSIS

DIAGNOSIS AND ETIOLOGY

The term *kyphoscoliosis* is derived from the Greek words *kuphos* and *scolios* (“humpback” and “crooked”) and refers to a group of disorders characterized by excessive spinal curvature in the lateral plane (scoliosis) and sagittal plane (kyphosis) as well as rotation of the spinal axis (Fig. 98-1). Scoliosis, which is defined as a lateral spinal curvature greater than 10 degrees, is generally associated with kyphosis and rotation of the spine around its long axis.¹ First described in detail by Hippocrates, kyphoscoliosis is one of the most common abnormalities of the spine, with an estimated prevalence for mild deformity of 1 in 1000 people and for severe deformity of 1 in 10,000 people in the United States.¹

Kyphoscoliosis is classified as idiopathic (no known cause), secondary or paralytic (associated with neuromuscular disease), and congenital (associated with vertebral malformation present at birth) (Table 98-1). Idiopathic kyphoscoliosis, the most common form, usually manifests in late childhood or early adolescence and involves females more often than males with a ratio of 4:1. Idiopathic kyphoscoliosis is often seen in multiple members of one

family. It is believed to be a multigene condition, with autosomal or sex-linked inheritance with variable phenotypic expression.¹ A defect in the chromatin-remodeling gene family, *CHD7*, and several other genetic loci have been associated with susceptibility to idiopathic kyphoscoliosis.^{2,3} The most important sequelae of progressive kyphoscoliosis are back pain, psychosocial problems, and development of respiratory failure.

The diagnosis of kyphoscoliosis is made by examining the chest wall. In severe cases, typical physical findings are the dorsal hump, which is due to angulated ribs and shoulder asymmetry, and the hip tilt, which is related to spinal rotation. In mild cases, the physical findings are more subtle. In children and adolescents, it is important to inspect the spine for asymmetry and to perform the Adam forward bend test. With this test, the examiner inspects the spine for thoracic or lumbar asymmetry while the patient bends forward at the waist until the spine becomes parallel to the floor. The Adam forward bend test can be used by community programs to screen for idiopathic kyphoscoliosis. When kyphoscoliosis is severe and complicated by right heart failure, clinical examination may reveal cyanosis, distended neck veins, peripheral edema, and hepatomegaly.

The diagnosis of kyphoscoliosis is confirmed by obtaining radiographs of the chest or spine. The severity of the spinal deformity can be assessed by measuring the Cobb angle of the vertebrae located within the spinal curvature.⁴ The Cobb angle is formed by the intersection of two lines, one parallel to the top and the other parallel to the bottom vertebrae of the scoliotic or kyphotic curves (Fig. 98-2). The greater the Cobb angle, the more severe the deformity. Angles greater than 100 degrees are usually associated with respiratory symptoms such as dyspnea on exertion, and angles greater than 120 degrees with respiratory failure.^{5,6}

PATHOPHYSIOLOGY

Pulmonary Function and Respiratory Mechanics

Kyphoscoliosis can produce the most severe restrictive impairment of all chest wall diseases (Table 98-2).⁷⁻¹⁰ A

Figure 98-1 Kyphoscoliosis. Chest CT reconstruction showing the rotation of the spine and rib cage in kyphoscoliosis. (Adapted from Chun EM, Suh SW, Modi HN, et al. The change in ratio of convex and concave lung volume in adolescent idiopathic kyphoscoliosis. *Eur Spine J* 17:224–229, 2008).

number of factors contribute to the severity of the restrictive impairment. With idiopathic kyphoscoliosis, restrictive lung physiology is invariably present when the Cobb angle is greater than 90 degrees.⁸ With such severe deformity, *total lung capacity* (TLC) and *vital capacity* (VC) may be reduced to as low as 30% of predicted values. In contrast, *residual volume* (RV) may be normal or slightly increased, resulting in an elevated RV/TLC ratio.^{8,11} In children with severe spinal deformity, hypoplastic lung may contribute to reduced lung volumes.^{12,13} Other factors contributing to the restrictive process include the number of vertebrae involved, thoracic location of the curve, patient age, presence of kyphosis, degree of spinal rotation, and presence of weak respiratory muscles.^{14,15}

The etiology of the kyphoscoliosis also influences the degree of respiratory impairment for any given Cobb angle. For example, in idiopathic kyphoscoliosis, those with Cobb angles less than 50 degrees usually have normal respiratory muscle strength whereas those with angles greater than 50

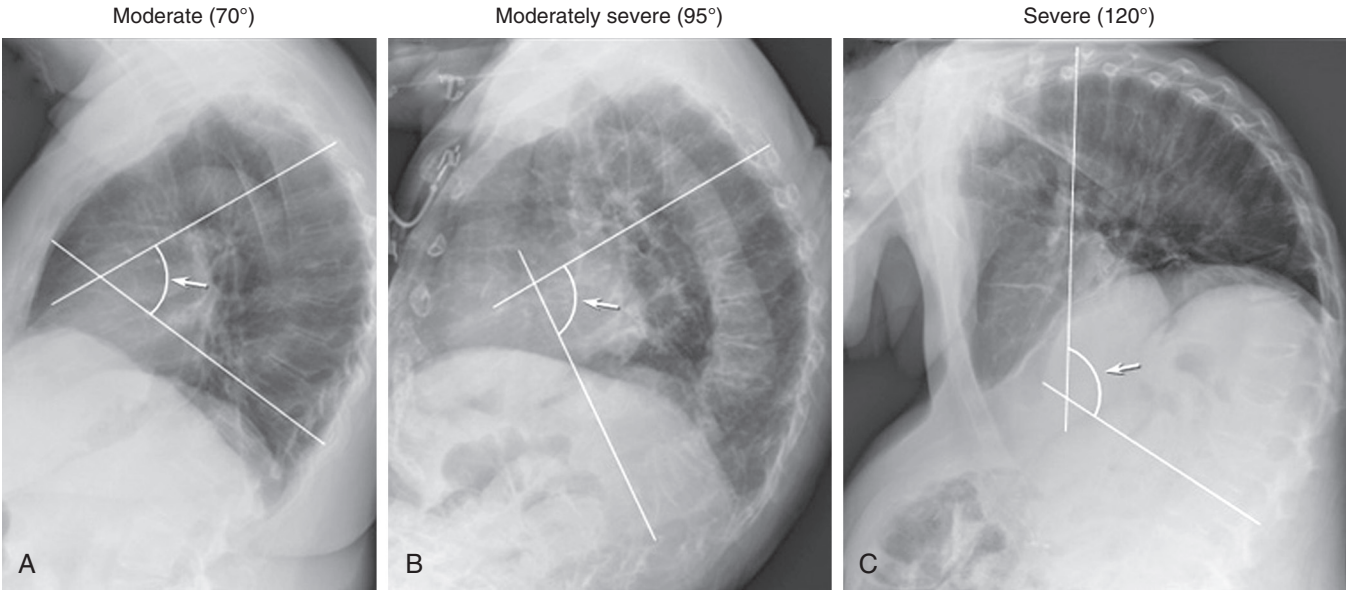

Figure 98-2 Different degrees of kyphoscoliosis showing the calculation of the Cobb angle on the lateral chest radiograph. Lines are drawn through the superior end plate of the vertebral body marking the cranial portion of the curve and the inferior end plate of the vertebral body marking the caudal portion of the curve. The angle of intersection between these two lines is the Cobb angle (arrow). Patients are shown with moderate (A), moderately severe (B) and severe (C) kyphoscoliosis along with their calculated Cobb angles. (Courtesy Michael Gotway, MD.)

degrees may show mild to moderate reductions in *maximal inspiratory pressure* (PI_{max}) and *maximal expiratory pressure* (PE_{max}) due to either respiratory muscle weakness or altered mechanical advantage of the muscles.^{14,16-18} In comparison, individuals with secondary (paralytic) kyphoscoliosis also have primary respiratory muscle weakness and therefore may have a profound degree of pulmonary restriction, even when the Cobb angle is less than 50 degrees.¹⁹ In general, perhaps because of this primary involvement of the respiratory muscles, individuals with paralytic kyphoscoliosis have a greater restrictive defect for a given degree of spinal deformity than those with idiopathic kyphoscoliosis.²⁰ Likewise, compared to those with idiopathic kyphoscoliosis, individuals with congenital kyphoscoliosis tend to have a greater restrictive impairment for a comparable degree of spinal deformity.²⁰ In general, in congenital kyphoscoliosis, the loss in VC is 15% greater than in patients with idiopathic kyphoscoliosis and a similar Cobb angle, most likely due to associated rib deformities and underlying lung abnormalities.²⁰

Table 98-2 Representative Values for Pulmonary Function and Respiratory Mechanics in Chest Wall Diseases

Parameter	KS	Post-Thor	PE	AS
TLC (% pred)	45	65	90	85
VC (% pred)	30	50	90	80
RV (% pred)	95	90	100	100
FEV ₁ (% pred)	40	40	95	80
FEV ₁ /FVC	80	60	80	75
CRS (% pred)	50	50	—	70
CCW (% pred)	30	40	—	60
CL (% pred)	60	50	80	80
PI_{max} cm H ₂ O	40	50	90	80
MVV L/min	37	37	107	80

AS, ankylosing spondylitis; CCW, compliance of chest wall; CL, compliance of lungs; CRS, compliance of respiratory system; FEV₁, forced expiratory volume in 1 second; FVC, forced vital capacity; KS, kyphoscoliosis; MVV, maximum voluntary ventilation; PE, pectus excavatum; PI_{max} , maximum inspiratory pressure; Post-Thor, post-thoracoplasty; RV, residual volume; TLC, total lung capacity; VC, vital capacity.

Representative values are from Bergofsky EH: Thoracic deformities. In Roussos C, editor: *The thorax*. New York, 1995, Dekker, pp 1915–1949.

Respiratory system compliance is reduced in kyphoscoliosis of any etiology, primarily due to the reduction in chest wall compliance and, to a lesser degree, a reduction in lung compliance due to microatelectasis.^{1,9,21,22} Cobb angles up to 50 degrees have minimal impact on respiratory compliance, whereas angles greater than 100 degrees may reduce compliance to levels seen in the adult respiratory distress syndrome.^{9,21,22} The stiff chest wall reduces the *functional residual capacity* (FRC). These factors combine to move the tidal breathing to a flatter, stiffer portion of the respiratory volume-pressure curve. This requires greater inspiratory effort for relatively small tidal breaths, which increases the work and oxygen cost of breathing (Fig. 98-3). The increase in the oxygen cost of breathing may reach values three to five times those measured in healthy individuals and thus place patients at risk for respiratory muscle fatigue.²³

Exercise Capacity

Those with mild idiopathic kyphoscoliosis usually have normal exercise capacity.^{14,24} If exercise is limited, it is typically due to deconditioning rather than diminished ventilatory reserve.^{17,24,25} In contrast, individuals with *moderate* idiopathic kyphoscoliosis (Cobb angles 25 to 70 degrees), *moderately severe* kyphoscoliosis (Cobb angles 70 to 100 degrees), or *severe* kyphoscoliosis (Cobb angles greater than 100 degrees) may have exercise limitation due to ventilatory constraints.^{17,25,26} With severe deformities (Cobb angles greater than 100 degrees), cardiovascular factors may further contribute to exercise limitation.^{25,27} Supplemental O₂ may improve oxygenation during exercise but usually does not affect walk distance.

Control of Breathing and Sleep-Disordered Breathing

The disordered chest wall geometry in patients with kyphoscoliosis constitutes an elastic load placed on the inspiratory muscles. To compensate for this increased load, these individuals adopt a rapid shallow breathing pattern consisting of low *tidal volumes* (V_T) and shortened *inspiratory time* (T_i).^{8,28} This breathing pattern reduces the *pressure needed to inhale* (P_{breath}) and minimizes the work per breath, thereby lowering the risk for developing respiratory muscle fatigue. Both parameters of rapid shallow breathing, V_T and T_i , decrease as the Cobb angle increases.²⁸ However, rapid

Figure 98-3 Schematic illustration of alterations in the volume-pressure relationship of the lung (L), chest wall (CW), and total respiratory system (RS) in kyphoscoliosis. In kyphoscoliosis, the chest wall is less compliant, leading to a reduction in functional residual capacity (FRC), and tidal breathing takes place on a flatter portion of the respiratory system volume-pressure curve. TLC, total lung capacity.

Figure 98-4 Idiopathic kyphoscoliosis. The relationship between alveolar ventilation and angle of scoliosis in patients with idiopathic kyphoscoliosis. (Adapted from Kafer ER: Idiopathic scoliosis. Gas exchange and the age dependence of arterial blood gases. *J Clin Invest* 58:825–833, 1976.)

shallow breathing has the negative consequence of increasing dead space ventilation and promoting microatelectasis. As an additional compensatory mechanism, patients with increased elastic load also increase neural drive to the respiratory muscles. Indirect evidence for this compensatory strategy is the elevated mouth occlusion pressure at 100 ms ($P_{0.1}$) seen during quiet breathing, exercise, or breathing stimulated by hypercapnia.^{28,29} As the degree of kyphoscoliosis increases, the neural output to the respiratory muscles increases. That is, $P_{0.1}$ correlates positively with the Cobb angle in these patients.²⁸ The increase in neural drive does not necessarily translate into increased minute ventilation because of the mechanical constraints imposed by the stiffened chest wall.

Hypoventilation is the most common sleep-related breathing disorder affecting individuals with kyphoscoliosis (Fig. 98-4). Hypoventilation results in hypercapnia and hypoxemia and is most severe during REM sleep when there is a reduction in neural drive to the respiratory muscles.^{30,31} Nocturnal hypoxemia typically predates the onset of respiratory failure in these patients and significantly impacts the clinical course and quality of life of patients with kyphoscoliosis.^{5,31} Adverse sequelae of nocturnal hypoxemia and hypercapnia include respiratory muscle dysfunction, persistent hypercapnia and hypoxemia, pulmonary vascular remodeling, pulmonary hypertension, and ultimately cardiorespiratory failure and death.³¹ Of note, the Cobb angle does not correlate with the magnitude of nocturnal oxyhemoglobin desaturation. Accordingly, it is important to screen for nocturnal hypoventilation with overnight oximetry even in patients with only moderate spinal deformity.³² Obstructive sleep apnea may be seen with a frequency similar to that in the general population and, if present, can further aggravate nocturnal hypoventilation.³³ Because sleep-related abnormalities and their effects on cardiorespiratory function are potentially treatable, they should always be evaluated in patients with kyphoscoliosis well in

advance of development of daytime hypercapnia so that noninvasive ventilation can be instituted early.^{31,33}

CLINICAL COURSE

The etiology of kyphoscoliosis is a major determinant of the clinical course.^{6,34} Idiopathic kyphoscoliosis has the most benign clinical course. Secondary kyphoscoliosis may progress rapidly, largely dependent on the underlying cause of neuromuscular weakness and age of onset of the spinal deformity. An early age of onset with rapid curve progression during growth and progression after skeletal maturity increase one's risk for serious respiratory complications.^{34,35} Congenital kyphoscoliosis may also progress rapidly.

In mild idiopathic kyphoscoliosis, the probability of developing respiratory failure with aging is similar to that in a healthy population. However, the risk is higher for patients with moderate or severe deformities. Large spinal curves at presentation, skeletal immaturity, and a thoracic, as opposed to a thoracolumbar or lumbar, location of the curve apex are generally considered risk factors for curve progression.⁶ The presence of respiratory muscle weakness enhances the likelihood of developing respiratory failure.⁸ In general, the spinal deformity worsens at a rate of about 1 degree per year in individuals with thoracic deformities greater than 50 degrees at skeletal maturity.³⁶

Individuals with severe idiopathic kyphoscoliosis and Cobb angles around 100 degrees should be monitored closely for respiratory complications, especially if they are middle-aged or older. Initially, individuals may experience dyspnea only with exertion but, as they age and the spinal deformity progresses, they may develop dyspnea even at rest. Cardiopulmonary problems and psychosocial concerns develop at a variable rate.⁶ When cor pulmonale develops, the prognosis is poor and, without therapy, death may supervene within one year. In addition to the degree of chest wall deformity, other factors that contribute to ventilatory failure in patients with idiopathic kyphoscoliosis are inspiratory muscle weakness, sleep-disordered breathing, and airway compression due to distortion of the lung parenchyma and twisting of airways. When respiratory failure develops in a patient with kyphoscoliosis and a Cobb angle less than 100 degrees, other causes for respiratory failure should be sought, particularly treatable causes such as sleep disordered breathing.

TREATMENT

Medical Treatment

General supportive measures include immunizations against influenza and pneumococci, smoking cessation, maintenance of a normal body weight, supplemental oxygen, and prompt treatment of respiratory infections. Physical activity should be encouraged to minimize deconditioning. Orthopedic braces have been used in skeletally immature patients with idiopathic kyphoscoliosis in an effort to prevent or correct the spinal deformity. A brace is generally recommended for growing children with angles between 25 and 40 degrees.^{37,37a}

Noninvasive nocturnal ventilation constitutes a major advance in the treatment of individuals with severe

kyphoscoliosis. Indications for instituting noninvasive nocturnal ventilation include symptoms suggestive of nocturnal hypoventilation or signs of cor pulmonale with either an elevated daytime arterial PCO_2 or nocturnal oxygen saturation less than 88% for 5 consecutive minutes (Table 98-3).³⁸ Either pressure or volume preset ventilators are effective in providing noninvasive ventilation.³⁹ Supplemental oxygen is indicated if hypoxemia persists despite correction of hypoventilation. For chronic respiratory failure, chest physiotherapy, bronchodilators, and diuretics may be needed in addition to noninvasive positive pressure ventilation. In those intolerant of noninvasive ventilation or unable to manage excessive bronchial secretions, tracheostomy constitutes another option.³⁹

The benefits of noninvasive ventilation are well established and include improvements in gas exchange, hemodynamic parameters, sleep architecture, quality of life, and perhaps survival (Table 98-4).^{39,40} Long-term noninvasive ventilation has been shown to reduce the number and duration of hospitalizations⁵ and possibly increase survival, although this evidence is not yet supported by randomized controlled studies.^{42,43} Interestingly, noninvasive ventilation does not appear to improve respiratory muscle strength or endurance; instead, noninvasive ventilation may improve respiratory failure by enhancing central chemosensitivity to carbon dioxide.⁴¹

Table 98-3 Indications for Instituting Long-Term Noninvasive Ventilation for Kyphoscoliosis (and other Chest Wall Diseases)

Symptoms (e.g., fatigue, morning headaches, dyspnea) or signs of cor pulmonale and one of the following:
 Daytime arterial $\text{PCO}_2 \geq 45$ mm Hg
 Nocturnal oxygen saturation $< 88\%$ for > 5 consecutive minutes
 Progressive neuromuscular disease with $\text{P}_{\text{Imax}} < 60$ cm H_2O or $\text{FVC} < 50\%$ of predicted

FVC, forced vital capacity; P_{Imax} , maximal static inspiratory pressure.
 Adapted from Consensus Conference: Clinical indications for noninvasive positive pressure ventilation in chronic respiratory failure due to restrictive lung disease, COPD, and nocturnal hypoventilation—a consensus conference report. *Chest* 116:521–534, 1999.

Table 98-4 Benefits of Noninvasive Nocturnal Ventilation in Chest Wall Diseases

GAS EXCHANGE

Increased arterial PO_2
 Decreased arterial PCO_2

HEMODYNAMICS

Decreased pulmonary arterial pressure
 Improved right ventricular function

MECHANICS

Reduced work of breathing
 Increased maximal inspiratory pressure (P_{Imax})

SLEEP HYGIENE

Normalized sleep patterns
 Fewer apneic episodes

OUTCOME

Fewer hospitalizations
 Improved quality of life
 Relief of dyspnea
 Possible increased survival

Surgical Treatment

In general, surgery involves fusion of the affected vertebral bodies via the posterior approach and the use of devices such as rods, wires, hooks, and pedicle screws to support the spine. This approach, which has seen significant advances since the initial introduction of implantable Harrington rods in the 1960s, allows for multiplanar correction, stable fixation with less spinal fusion, and early postoperative mobilization without a cast or brace.⁶ Newer nonfusion techniques use growth-friendly rods such as expandable spinal rods, titanium rib implants, or remotely operated magnetic growth rods.^{44,45} Surgery is currently recommended in individuals with skeletal immaturity and a Cobb angle greater than 45 degrees.³⁷

The benefits of spinal surgery on pulmonary function remain unclear.^{46,47} Immediately following surgery, pulmonary function may be impaired due to rib cage trauma and changes in the chest wall caliber.²¹ In the long-term, pulmonary function is more likely to improve in young children and adolescents than in adults. In the absence of randomized controlled studies assessing the efficacy of surgery, the overall role of surgical management in restoring function and minimizing the possibility of respiratory failure is not clear.^{6,48,49}

THORACOPLASTY

Before the advent of effective antituberculosis chemotherapy, thoracoplasty was commonly employed to reduce lung volume as a way to control pulmonary tuberculosis. Thoracoplasty reduced lung volume using a variety of means: removing or fracturing ribs (Fig. 98-5), resecting the phrenic nerve, or filling the pleural space with foreign material (i.e., Lucite spheres [Fig 98-6], oil [Fig. 98-7], and ping

Figure 98-5 Thoracoplasty. Frontal chest radiograph in a patient with history of prior *Mycobacterium tuberculosis* infection shows extensive deformity of the left hemithorax consistent with prior thoracoplasty. Scoliosis of the thoracic spine is probably secondary to the chest wall deformity.

Figure 98-6 Lucite sphere plombage. Frontal (A) and lateral (B) chest radiographs show regular lucencies (arrowheads) representing Lucite sphere plombage in a patient with prior left upper lobe *Mycobacterium tuberculosis* infection. (Courtesy Michael Gotway, MD.)

pong balls). Severe restrictive impairment may manifest itself decades after the procedure; after several years without symptoms, individuals may become dyspneic, initially with exertion and then at rest, and may eventually develop chronic respiratory failure. Factors such as slowly progressive kyphoscoliosis, in part, account for the delay in the onset of symptoms. The severity of the restrictive defect, which can be similar to that seen in kyphoscoliosis (see Table 98-2), may be due to a reduction in respiratory system compliance, fibrothorax, lung resection, phrenic nerve damage, scoliosis, and lung fibrosis related to prior underlying granulomatous disease.^{50,51}

Since this procedure was abandoned for tuberculosis therapy after the 1950s, very few post-thoracoplasty

patients are alive today.^{50,51} However, knowledge of the sequelae of thoracoplasty is of more than historical interest. Thoracoplasty is occasionally still performed to treat bronchopleural fistulas that have failed to close following decortication or persistent empyema in which decortication is not feasible or has failed to eradicate the infection.⁵² Surgery similar to thoracoplasty includes aggressive surgery on the rib cage, as may be performed to resect tumors.⁵³ Such surgeries may stiffen the chest wall and lead to an increase in the work of breathing, impaired gas exchange, and ultimately cor pulmonale. As with severe kyphoscoliosis, the treatment consists of oxygen, antibiotics when appropriate, and noninvasive nocturnal mechanical ventilation. Patients undergoing extensive chest wall surgery of any type should have their pulmonary function monitored periodically.

PECTUS EXCAVATUM

DIAGNOSIS AND ETIOLOGY

Pectus excavatum is a common congenital chest wall deformity characterized by excessive depression of the sternum and its adjacent costal cartilages (Fig. 98-8).⁵⁴ It is the most common chest wall deformity, seen in approximately 0.5% to 2% of the population, more frequently in males than in females (ratio 4:1).^{54,55} Diagnosed by inspecting the rib cage, pectus may be apparent in infancy but, in most cases, becomes noticeable at puberty.

Pectus excavatum may result from abnormal cartilage growth displacing the sternum inward.⁵⁵ A genetic predisposition is supported by a large study in which 43% of patients with this deformity gave a family history of pectus excavatum.⁵⁶ Approximately 6% of patients have a connective tissue disorder such as Marfan or Ehlers-Danlos syndromes, and 40% to 60% have scoliosis.⁵⁷ Congenital heart disease may coexist in roughly 2% of cases.^{54,55}

The magnitude of sternal deformity is best assessed by computed tomography (CT) of the chest. The transverse (Tr)

Figure 98-8 Pectus excavatum. **A**, Individual with severe pectus excavatum deformity. **B**, MR imaging of the same individual showing compression of the right ventricle by the deformity. **C**, The Haller index is calculated on chest CT images by the ratio of the transverse diameter and the anteroposterior diameter of the rib cage at the level of the deepest sternal depression. In this patient, the Haller index is 4.8.

Figure 98-9 Pectus excavatum with right ventricular compression. Sequential steady-state free-precession axial MR images show right ventricular compression by the sternum (arrowheads) induced by the pectus deformity (* = right atrium, ⊙ = right ventricle). Images **A** through **D** were taken at different times in the cardiac cycle. (Courtesy Michael Gotway, MD.)

and anteroposterior (AP) diameters of the rib cage are measured at the level of the deepest sternal depression. The normal Tr/AP ratio, also known as the Haller index, is 2.5 or less (see Fig. 98-8). A Haller index of greater than 3.25 indicates a significant pectus deformity that may need surgical correction.⁵⁸ Individuals with a significant deformity commonly have cosmetic complaints and, in addition, 30% to 70% of individuals may complain of exercise limitation or dyspnea with exertion, often out of proportion to recognized abnormalities in cardiopulmonary function.

PATHOPHYSIOLOGY

Respiratory Mechanics and Exercise Capacity

Most patients with pectus excavatum have normal pulmonary function with a normal mobility of the rib cage.^{59,60}

Occasionally, patients will have a mild restrictive deficit,^{55,57} often when there is concomitant scoliosis.⁶¹ Cardiopulmonary exercise testing is usually normal, although those with the most severe deformities may exhibit a mild reduction in maximal work rate and oxygen consumption.^{62,63} Although the concept is not widely accepted, right ventricular compression by the depressed sternum (Fig. 98-9 and Video 98-1) may be a mechanism contributing to exercise limitation in some individuals.⁶⁴

TREATMENT

Surgical correction of pectus excavatum is usually considered for patients with a Haller index greater than 3.5 in conjunction with symptoms or evidence of cardiac or pulmonary impairment.^{55,65,65a} The modified Ravitch procedure consists of resection of costal cartilage and a sternal

osteotomy, with or without fixation of the sternum by external or internal supports.⁵⁸ The less invasive Nuss procedure entails placing a curved metal rod under the sternum through small incisions on each side of the rib cage. The rod is rotated under the sternum forcing and holding it outward; the rod is removed after 2 to 4 years once the sternum is stabilized in its proper position.⁶⁶ The rate of complications does not differ significantly between these surgical approaches.⁶⁷ Another minimally invasive procedure under investigation uses magnets to pull out the sternum and correct the deformity gradually, in a fashion analogous to that of braces, which gradually correct the position of teeth.⁶⁸ Complications of procedures that involve cartilage resection include sternal necrosis, infection, or recurrence of the deformity. With corrective procedures, improvement of symptoms and function is difficult to predict. To date, there is no convincing evidence that correction of the deformity improves either cardiopulmonary function or exercise capacity.⁶⁹⁻⁷¹

FLAIL CHEST

DIAGNOSIS AND ETIOLOGY

Flail chest arises when a segment of the rib cage moves inward rather than outward during inspiration⁷² (Video 98-2). Production of a flail segment of chest wall requires multiple rib fractures, specifically double fractures of three or more contiguous ribs or combined sternal and rib fractures, to uncouple the segment from the surrounding chest wall. An unstable segment of the chest wall can also result from multiple single rib fractures along a straight line that partially uncouples the segment from the surrounding chest wall. This condition is referred to as “nonintegrated chest wall” rather than “flail chest.”⁷³

The most common cause of flail chest is blunt chest trauma.⁷² Flail chest is most commonly seen after automobile accidents and falls, although it may also develop after aggressive cardiopulmonary resuscitation or in patients with pathologic rib fractures.^{74,75} In children, flail chest is infrequent because the chest wall is more compliant; thus, when a child does have a flail chest, it signifies a much greater degree of trauma.⁷⁶ Rarely, flail chest may complicate corrective rib resection or appear in neonatal life due to congenital rib abnormalities.^{77,78}

The diagnosis of flail chest is made by examining the rib cage and noting the characteristic paradoxical movement of a chest wall segment inward rather than outward during inspiration (and outward rather than inward during expiration) with spontaneous breathing (Fig. 98-10 and see Video 98-2). In subtle cases, the paradoxical motion of the flail chest can be appreciated by palpation of the chest wall. Chest radiographs may confirm the presence of multiple rib fractures; however a three-dimensional reconstruction of a chest CT is a more sensitive technique for identifying rib fractures and the other pulmonary injuries, such as pulmonary contusion or hemothorax related to chest wall trauma.⁷⁹ In the mechanically ventilated trauma patient, the diagnosis of flail chest may be delayed for days or even weeks and become apparent only after withdrawal of sedation and resumption of spontaneous breathing.⁸⁰

Figure 98-10 Flail chest. Tracings derived from magnetometers depict normal and different patterns of chest wall motion seen in two patients with flail chest. In each patient, at the point of maximal inspiration (dotted line), a portion of the rib cage moves paradoxically. In the patient with a paradox of the upper rib cage (URC) and lower rib cage (LRC), the URC and LRC segments move inward (downward tracing) with outward movement of the abdomen and transverse rib cage (TRC). In the patient with a paradox of the transverse rib cage, the TRC is the only segment moving inward with inspiration. (Modified from Tzelepis GE, McCool FD, Hoppin FG Jr: Chest wall distortion in patients with flail chest. *Am Rev Respir Dis* 140:31–37, 1989.)

TRAUMA AND FLAIL CHEST

The presence of flail chest following trauma signifies severe thoracic injury and is an independent risk factor for respiratory complications, respiratory failure, and death.^{76,81,82,82a} Patients with flail chest may have pulmonary complications such as lung contusion, pneumothorax, or hemothorax.^{76,81,82} Flail chest and its associated pain promote atelectasis, impair cough, and may lead to respiratory failure. Patients with flail chest are twice as likely to develop respiratory failure and require mechanical ventilation as patients with isolated lung contusion.^{76,82}

The presence of flail chest is thus associated with a poor prognosis and should alert the clinician that there may be traumatic injury to other organs. The presence of flail chest is a marker of increased mortality both in patients with isolated chest wall trauma and in patients with multiple sites of trauma. Without flail chest, mortality from chest wall trauma ranges from 7% to 14%; with concomitant flail chest, mortality increases further.^{76,82} Similarly, in patients with multiple sites of trauma, mortality is roughly 30%; in those with concomitant flail chest, mortality may be as high as 68%.^{76,82} The high mortality associated with flail chest is in part due to coexistence of other injuries such as fractures of long bones or vertebrae, head trauma, rupture of major vascular structures, or laceration of abdominal organs. Concomitant head injury and age older than 65 years are particularly poor prognostic factors in patients with traumatic flail chest.^{81,83} In patients who survive the acute injury, chronic disability related to flail chest may develop, with chest tightness, chest pain, or dyspnea on exertion. However, with operative fixation of the flail segment even years after the injury, these symptoms can improve dramatically.^{80,84}

PATHOPHYSIOLOGY

Respiratory Mechanics

Flail chest disrupts the anatomic and functional integrity of the chest wall and can seriously alter its function. With flail chest, a segment of the chest wall is uncoupled from the forces that expand the rib cage. Consequently, this

uncoupled segment moves passively with the variations of pleural pressure. With inspiration and the decrease in pleural pressure, the flail segment moves inward and, during expiration with less negative pleural pressure, it moves outward. If the normal swings in pleural pressure are amplified by a decrease in lung compliance due to concomitant pulmonary contusion and/or atelectasis, the paradoxical motion of the flail segment can increase.

The location of the flail segment is dependent on the site of rib fractures. The most common location is the lateral rib cage. However, for any flail segment, one may see different patterns of movement. For example, motion may be paradoxical within the rib cage itself or between the rib cage and the abdomen (see Fig. 98-10).⁸⁵ The degree of paradoxical motion may also differ at different locations. Posterior rib fractures exhibit less paradoxical motion due to splinting provided by the paraspinal muscles. Normal recruitment patterns of the intercostal muscles may be altered because of severe chest wall pain and may increase or decrease the degree of rib cage paradox.^{86,87} Different pain-induced respiratory muscle recruitment patterns may explain why some cases of flail chest remain unstable following prolonged mechanical ventilation^{88,89} and why lateral flail segments have a higher propensity for dislocation following surgical fixation.^{88,89}

Respiratory Failure

The pathogenesis of respiratory failure in flail chest is multifactorial; hypoventilation due to pain, flail-induced impairment in respiratory muscle function, and concomitant lung injury all play a role. The simplistic theory that respiratory failure resulted from the movement of air back and forth from the injured to uninjured side (*pendelluft*) has been abandoned. A flail segment has important physiologic consequences, even in the absence of contusion. First, pain impairs cough and promotes shallow tidal breathing, both of which may lead to atelectasis. Second, the flail segment impairs respiratory muscle performance.⁸⁵⁻⁸⁷ The paradoxical motion of the chest wall increases the degree of muscle shortening for a given tidal volume and, because the muscles are shortening further, the work they perform is increased per breath.⁸⁵ Increased work of breathing, together with an inefficient use of respiratory muscles increase the oxygen cost of breathing. When these factors are compounded by increases in elastic loads related to lung contusion and/or atelectasis along with hypoxemia, the respiratory muscles are predisposed to fatigue and respiratory failure or weaning difficulties (Fig. 98-11).^{23,85}

Pulmonary Function Tests

Forced vital capacity (FVC) and **FRC** are reduced immediately following trauma sufficient to cause flail chest. VC may be reduced to 50% of predicted. These reductions are related to pain, disordered chest wall motion, and underlying lung contusion. In patients with flail chest without lung contusion treated conservatively, FVC and FRC generally return to baseline values within 6 months of the acute injury. In contrast, in patients with flail chest complicated by lung contusion treated conservatively, pulmonary function may be reduced up to 4 years after injury, most likely due to fibrosis of the contused area. Compared with conservative management, operative fixation of flail chest may be a

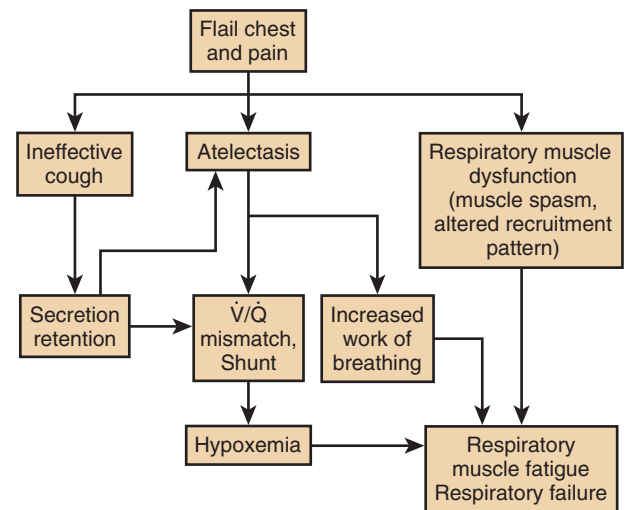

Figure 98-11 Factors involved in the pathophysiology of respiratory failure in flail chest.

better option to preserve pulmonary function, as indicated from both controlled⁹⁰ and uncontrolled studies.⁸⁹

TREATMENT

General Aspects

The restoration of anatomic and functional integrity of the chest wall is a key for avoiding complications related to flail chest. Surgical and nonsurgical approaches can be used to stabilize the flail segment (Fig. 98-12). Nonsurgical management is based on administration of adequate analgesia, clearing of bronchial secretions, and mechanical ventilatory assistance if needed.⁹¹ Control of pain is crucial in averting atelectasis and achieving an effective cough. Adequate pain relief can be accomplished by oral medications, patient-controlled analgesia pumps, intercostal nerve blocks, or epidural anesthesia.⁹¹ Adequate analgesia in combination with supplemental oxygen, effective tracheo-bronchial toilet, and cautious fluid replacement, often results in successful treatment of flail chest and avoidance of respiratory failure. If needed, mechanical ventilation can act as a pneumatic splint to stabilize the flail segment by keeping pleural pressure positive. However, mechanical ventilation delivered via a tracheostomy or endotracheal tube solely for the purpose of providing stability to the chest wall is not recommended due to the increased morbidity and mortality associated with mechanical ventilation. In contrast, positive pressure ventilation delivered noninvasively via a nasal or face mask to patients who are spontaneously breathing and able to protect their upper airway provides an alternate means of stabilizing the flail segment.⁹¹ Noninvasive ventilation, in conjunction with patient-controlled analgesia, improves gas exchange, allows for early patient mobilization and access for physiotherapy, and significantly reduces morbidity and mortality when compared with mechanical ventilation.^{92,93} If intubation and mechanical ventilation is needed, a low impedance ventilator mode that minimizes the likelihood of generating subatmospheric pleural pressure are optimal choices for stabilizing the flail segment and for weaning.⁸⁵

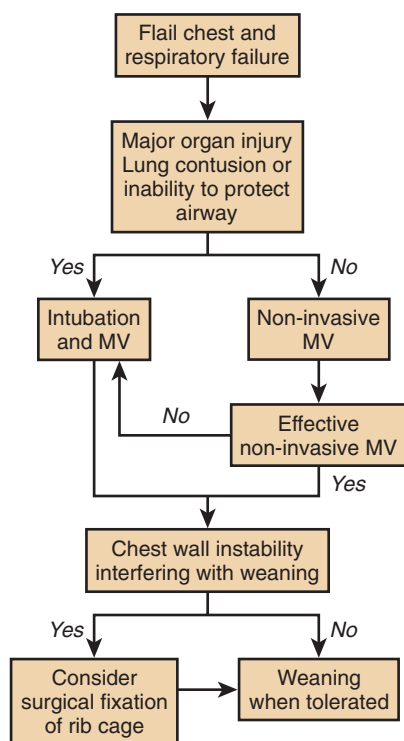

Figure 98-12 Algorithm for the management of acute respiratory failure due to flail chest. MV, mechanical ventilation.

Surgical procedures that are used to stabilize a flail segment include mobilization of large chest wall flaps, or inserting devices such as medullary wires or nails, Judet struts, or titanium plates to stabilize the rib cage.^{72,94} The few controlled studies that are available suggest that surgical fixation may be superior to conservative management by reducing the need for ventilatory support, lowering the infection rate, and minimizing the duration of intensive care unit stay.⁹⁵⁻⁹⁸ The indications for operative fixation of flail chest are not fully defined; candidates may be those with flail chest who are unable to be weaned from mechanical ventilation due to chest wall instability, those undergoing thoracotomy for concurrent injuries, those with persistent pain or severe chest wall instability, or those with a progressive decline in pulmonary function.^{72,90,91,97,98} The indications for surgical stabilization need to be clarified by randomized well-controlled studies.^{97,98a}

ANKYLOSING SPONDYLITIS

DIAGNOSIS AND ETIOLOGY

Ankylosing spondylitis (AS) is a chronic progressive inflammatory disease involving primarily the ligamentous structures of the spine, the sacroiliac joint, and large peripheral joints.⁹⁹ It usually affects men, with the most common age of onset between 15 and 25 years. The annual incidence is 6.6 per 100,000 white Americans and three to four times less in African Americans. There is a genetic predisposition for the disease, with nearly 95% of white patients positive for the HLA-B27 antigen.⁹⁹ Chronic inflammation eventually leads to fibrosis and ossification of the spine and

Figure 98-13 Representative plots of the rib cage and abdominal displacements during quiet breathing in a seated patient with ankylosing spondylitis, before and at various time points during therapy with anti-tumor necrosis factor α . Note the diminished contribution of the rib cage to tidal volume at baseline and the progressive increase in the rib cage contribution to breathing with treatment, becoming closer to the normal patterns obtained about 2 weeks apart in a healthy individual (control). B, baseline; M, months. (Adapted from Tzelepis GE, Kalliakosta G, Tzioufas AG, et al: Thoracoabdominal motion in ankylosing spondylitis: association with standardized clinical measures and response to therapy. *Ann Rheum Dis* 68:966-971, 2009.)

adjacent structures as well as of the costovertebral and sternoclavicular joints.

PATHOPHYSIOLOGY

Respiratory Mechanics

AS impairs chest wall function by limiting rib cage motion (Fig. 98-13).¹⁰⁰ This limited motion is due to stiffening and fusion of the costovertebral and sternoclavicular articulations (Fig. 98-14), to rigidity of the spine (Fig. 98-15), and possibly to intercostal muscle atrophy with advanced disease.¹⁰¹ Despite a pronounced reduction in rib cage mobility, lung compliance remains normal except in cases with fibrobullous (Fig. 98-16) or interstitial lung disease.^{101,102} Because the abdomen is compliant while the rib cage is stiff, the lung expands preferentially by caudal descent of the diaphragm and abdominal displacement than by expansion of the rib cage (i.e., the lung expands along the “path of least resistance”).^{103,104} This strategy likely minimizes the work and energy needed to inflate the lung.¹⁰⁴ Thus, during quiet breathing, exercise, or speech, the lung volume changes mostly by caudal displacement of the diaphragm and expansion of the abdominal wall.^{101,103,104} It has been found that transdiaphragmatic pressure increases by 2.4-fold in patients with AS at levels of ventilation at which healthy individuals increase transdiaphragmatic pressure by 1.4-fold.¹⁰¹

Pulmonary and Respiratory Muscle Function

Restrictive lung disease may be seen in patients with AS. Mild reductions in TLC and VC may be related to disease activity and duration, to spinal and rib cage immobility, or to concomitant kyphosis.^{100,105} Kyphosis may develop in up to 50% of patients with long-standing AS due to either advanced disease or osteoporosis.¹⁰⁶ Kyphosis may be worsened and respiratory function further impaired by fractures involving the rigid spine (Fig. 98-17).¹⁰⁷ Patients with AS are also at risk for respiratory failure if cervical spine fractures (typically C6 or C7) cause tetraplegia.

Figure 98-14 Ankylosing spondylitis. Bone scan in a patient with ankylosing spondylitis shows increased uptake (arrows) in the sternoclavicular and manubriosternal joints. (Adapted from Ramonda R, Lorenzin M, Lo Nigro A, et al: Anterior chest wall involvement in early stages of spondyloarthritis: advanced diagnostic tools. *J Rheumatol* 39:1844–1849, 2012.)

Respiratory muscle strength and endurance may be reduced in AS. PI_{max} and PE_{max} may be mildly reduced and respiratory muscle endurance may be impaired even in individuals with normal respiratory muscle strength.^{100,108,109} Mild reductions in strength and endurance may be related to intercostal muscle atrophy secondary to decreased rib cage mobility¹⁰¹ or to poor coordination of the respiratory muscles.¹¹⁰

Gas Exchange and Exercise Capacity

Regional ventilation is usually normal despite the limited expansion of the rib cage.¹¹² However, a mild impairment in gas exchange may be seen along with a reduction in DL_{CO} likely related to a mild reduction in lung volumes.¹⁰⁰ However, when fibrobullous disease (see Fig. 98-16) is present, gas exchange may be severely compromised and arterial PO_2 reduced.¹¹¹

Exercise capacity may be reduced in patients with AS.¹⁰⁸ The reduction in exercise capacity may be related more to deconditioning than to a limitation of ventilation because maximal oxygen consumption does not correlate with the degree of rib cage expansion.¹⁰⁸

Interstitial Lung Disease

Fibrobullous upper lobe disease is present in 1% to 4% of patients with AS (see Fig. 98-16).¹¹¹ The cause of apical fibrobullous disease is unknown. Possible causes include diminished upper lobe ventilation and apical mechanical stress due to thoracic rigidity, as well as recurrent pulmonary infections due to impaired cough. Fibrobullous disease may be unilateral or bilateral and affects males more than females. The spectrum of disease ranges from minimal upper lobe interstitial opacities to marked fibrosis, honeycombing, and cavitory lesions that may be mistaken for tuberculosis.¹¹¹ In a limited number of cases, histologic examination has revealed prominent interstitial fibrosis with hyaline and elastic degeneration of collagen, and

Figure 98-15 Ankylosing spondylitis: fused thoracic spine. Lateral chest radiograph (A) and sagittal reformatted chest CT myelogram image from a different patient (B) show flowing syndesmophytes (arrowheads) representing ossification of the outer fibers of the annulus fibrosis, bridging one vertebral body corner to another. When accompanied by longitudinal ligament ossification, fusion and kyphosis of the spine result. (Courtesy Michael Gotway, MD.)

Figure 98-16 Ankylosing spondylitis: upper lobe fibrobullous disease. (Courtesy Michael Gotway, MD.)

absence of granulomas.¹¹¹ Patients are usually asymptomatic but, with severe disease, they may develop dyspnea and be at risk for spontaneous pneumothorax, aspergillosis (Fig. 98-18) or mycobacterial infection. Corticosteroids do not prevent progression of the disease. Because lung resection can be complicated by bronchopleural fistula in 50% to 60% of patients,¹¹¹ it is only recommended for treatment of major hemoptysis.¹¹¹ Another 10% to 20% of patients with AS develop nonapical interstitial lung disease, which can be detected by high-resolution CT scans of the chest.¹¹³

TREATMENT

The use of biological agents has constituted a significant advance in the treatment of AS.^{114,115} The TNF- α antagonists (infliximab, etanercept, adalimumab, and golimumab) provide symptom relief, reduce spinal inflammation, and improve the quality of life in these patients.¹¹⁴⁻¹¹⁶ Anti-TNF- α therapy can be shown to improve rib cage mobility resulting in greater ribcage and less abdominal displacement during tidal breathing (see Fig. 98-13).¹⁰⁴ In addition, exercise and physical therapy are key components of standard care.¹¹⁷ Cardiorespiratory fitness and spinal mobility may be enhanced by exercise and physiotherapy programs.^{99,118,118a} Tobacco use should be avoided. Patients should be monitored with baseline chest radiography and spirometry and receive repeat studies should respiratory symptoms develop. For patients treated with anti-TNF- α agents, a high index of suspicion for possible reactivation of latent tuberculosis is required.¹¹⁹ If intubation is planned, it should be performed with caution because these patients are at increased risk for spinal cord injury because

Figure 98-17 Ankylosing spondylitis: fused thoracic spine complicated by fracture. Sagittal T1-weighted (**A**) and T2-weighted (**B**) MRI shows irregular intermediate and centrally low signal (*arrow*) extending transversely through the intervertebral disc space, associated with kyphosis centered at this level. Note that the injury extends into the posterior elements (*arrowheads*); this pattern of spinal fracture is common in ankylosing spondylitis. The T2-weighted image (**B**) shows increased signal in the involved vertebral bodies consistent with bone marrow edema, and reveals spinal cord compression. Sagittal reformatted image from a chest CT in a different patient (**C**) shows a similar three-column fracture pattern, although more severe, complicated by distraction and displacement; note anterior widening of the intervertebral disc space (*arrowheads*). (Courtesy Michael Gotway, MD.)

Figure 98-18 Ankylosing spondylitis: fibrobullous disease complicated by mycetoma. Frontal chest radiograph in a patient with ankylosing spondylitis and upper lobe fibrobullous disease (**A**) shows an irregular mass-like opacity at the left lung apex (arrow, **A**), with lucency (arrowheads, **A**) along the cranial margin of the opacity. Axial chest CT displayed in lung windows (**B–D**) confirms the presence of the opacity (arrows, **B–D**) within the cavity (arrowheads, **B–D**) in the left apex, consistent with mycetoma. (Courtesy Michael Gotway, MD.)

hyperextension of a rigid cervical spine may lead to fracture and, rarely, of upper airway compromise due to involvement with fixation of the cricoarytenoid joint.

OBESITY

DIAGNOSIS AND ETIOLOGY

Obesity is a major health problem throughout the world.¹²⁰ It is estimated that two thirds of the U.S. population are either overweight or obese.¹²¹ Approximately \$168 billion or 16.5% of the total health care budget is spent annually to treat obesity and obesity-related comorbidities.¹²² Body fat usually constitutes 15% to 20% of body mass in healthy men and 25% to 30% in healthy women. In obesity, the body fat content may increase by as much as 800% in men and 500% in women.¹²³ Fat-free mass also increases in obese individuals, accounting for 15% to 30% of the total weight gain.^{124,125} A number of parameters have been used to assess obesity, the most common being *body mass index* (BMI), which is calculated as the *body weight* (BW) in kilograms divided by the square of the *height* (Ht) in meters (BW/Ht^2). (The BMI can also be calculated as the body weight in pounds multiplied by 703 and divided by the square of the height in inches.) Individuals with a BMI between 18.5 and 24.9 kg/m^2 are normal, with a BMI between 25 and 29.9 kg/m^2 are overweight, and with a BMI greater than 30 kg/m^2 are obese. Obesity is severe (morbid) when the BMI is greater than 40 kg/m^2 .¹²⁰

Overweight and obese individuals are at greater risk for death than healthy individuals with a normal BMI.^{126,127} When compared with those with a normal BMI, the overweight have a 20% to 40% higher risk for death and the obese have a 300% to 400% higher risk for death.¹²⁶

Morbidity also increases as BMI increases¹²⁶ and is primarily due to cardiovascular and respiratory factors, with intra-abdominal fat constituting an independent risk for cardiovascular disease.^{128–130}

The most frequent respiratory complaints of obese individuals are dyspnea and exercise intolerance.¹³⁰ These complaints may be related to abnormal pulmonary function, disordered respiratory control, and elevated levels of mediators of inflammation, such as those linking obesity to airway hyperresponsiveness.^{130a} The severity of the respiratory impairment may not correlate with the degree of obesity.

PATHOPHYSIOLOGY

Obese individuals with the same BMI may exhibit different abnormalities in respiratory function. In particular, in some obese individuals, the arterial PCO_2 may be normal while, in others with the same BMI, the PCO_2 may be elevated. Indeed, the level of arterial PCO_2 is used to distinguish obese individuals who have *simple obesity* (SO; individuals who are eucapnic), from those who have *obesity hypoventilation syndrome* (OHS; individuals who retain CO_2). In addition, pulmonary function, respiratory mechanics, gas exchange, respiratory control, and exercise capacity may be significantly different in patients with SO and OHS.

Pulmonary Function

In obesity, the most common abnormalities of pulmonary function are reductions in *expiratory reserve volume* (ERV) and *FRC*¹³¹ (Fig. 98-19). For each unit increase in BMI from 20 to 30 kg/m^2 , FRC and ERV decrease by approximately 3% and 5%, respectively; thereafter, for each unit increase in BMI, both FRC and ERV decrease approximately 1%.¹³¹ Consequently, an individual with a BMI of 30 kg/m^2 can

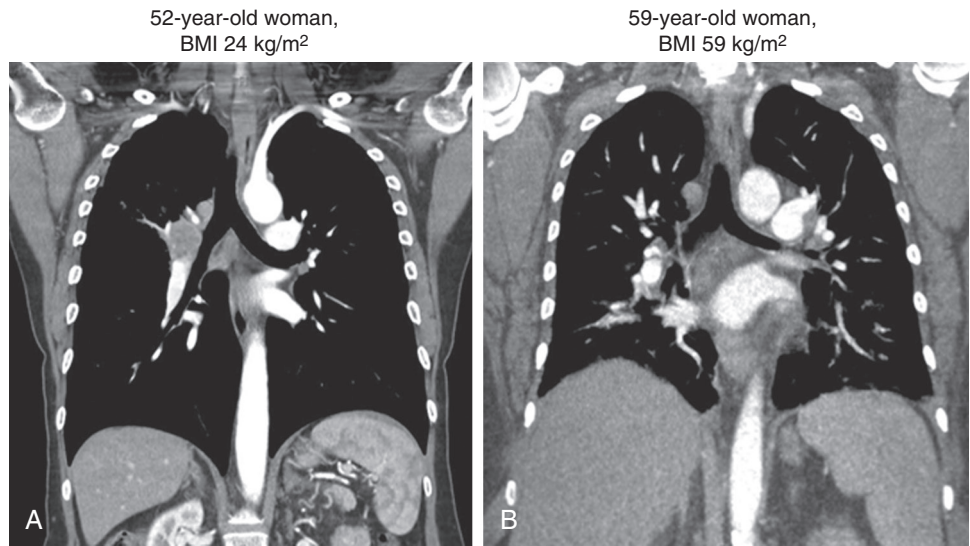

Figure 98-19 Coronal CT images of a non-obese (A) and an obese (B) individual of similar height, age, and predicted total lung capacity. The lung volume of the obese individual (B) is noticeably less than that of the non-obese individual (A). This may be due to the added load of excess fatty tissue on the respiratory system, which is most pronounced in the supine position. Typically, functional residual capacity and expiratory reserve volume are most affected with obesity.

Table 98-5 Representative Values of Respiratory Pathophysiology of Simple Obesity and Obesity Hypoventilation Syndrome			
Parameter	Normal	Simple Obesity	Obesity Hypoventilation
BW (% ideal)	100	200	200
BMI (kg/m ²)	24	45	45
TLC (% pred)	100	95	80
CRS (L/cm H ₂ O)	0.10	0.05	0.06
Rrs (cm H ₂ O•L ⁻¹ •s ⁻¹)	1.2	4.0	7.8
Work of ventilation (J/L)	0.43	0.74	1.64
MVV (L/min)	160	130	90
PI _{max} (cm H ₂ O)	100	95	60

BMI, body mass index; BW, body weight; CRS, compliance of the respiratory system; J, joule; MVV, maximum ventilatory volume; PI_{max}, maximal static inspiratory pressure; Rrs, respiratory system resistance; TLC, total lung capacity.
Adapted from Rochester DF: Obesity and abdominal distention. In Roussos C, editor: *The thorax*. New York, 1995, Dekker, pp 1950–1973.

be expected to have an FRC of approximately 75% of predicted and an ERV of only 47% of predicted.¹³¹ The FRC is reduced by adipose tissue compressing the rib cage and abdomen thereby reducing the outward elastic recoil of the chest wall and shifting the balance of recoil between the lung and chest wall to lower lung volumes. Because RV is affected to a lesser extent than FRC, ERV is preferentially reduced.¹³²⁻¹³⁴ In patients with OHS, FRC and ERV may be reduced even further.^{135,136}

While TLC, VC, and RV may be normal or only minimally reduced in individuals with SO, they may be significantly reduced (TLC and VC < 80% of predicted) in those with OHS or morbid obesity (Table 98-5).^{135,136} Because pulmonary function is more severely affected in OHS than in SO, factors other than the BMI must be involved. The more substantial

reductions in TLC and VC in those with OHS may be due to weakness of the respiratory muscles.¹³⁷ In addition, the distribution of fat may contribute to differences in lung volumes. For example, the distribution of body fat to the upper body (central fat distribution) impairs pulmonary function more than a distribution to the lower body (below the hips).¹³⁸⁻¹⁴⁰ Upper body fat distribution is indicated by a waist circumference of 35 inches (89 cm) or more for women and 40 inches (102 cm) or more for men.¹³⁸⁻¹⁴⁰ The correlation of respiratory impairment with upper body fat appears to be more apparent in men than in women.¹³⁸ The single-breath diffusion capacity is usually normal or increased in simple obesity and slightly reduced in OHS.¹⁴¹ Other tests of pulmonary function such as the FEV₁/FVC ratio, MVV, peak inspiratory flow rate, and the ratio of dead space to tidal volume (V_D/V_T) are usually normal.^{135,136}

Respiratory Mechanics

Obesity reduces *respiratory system compliance* (CRS), primarily by lowering lung compliance.^{133,142-145} In SO, values for CRS are approximately 80% to 90% of normal and are further reduced as BMI increases or when changing from the upright to supine position.^{133,142-145} In OHS, CRS is generally less than 45% of normal.¹⁴⁶ The reduced compliance is thought to be due to the weight of adipose tissue forcing FRC and tidal breathing to low lung volumes, near RV, where the lung is stiff due to airway closure.^{133,142,143} In addition, the excess chest wall adipose tissue creates a threshold load by making pleural and alveolar pressure less subatmospheric or even positive at end-expiration (*intrinsic positive end-expiratory pressure*, PEEPi).¹⁴² The inspiratory muscles must lower pleural pressure sufficiently to overcome PEEPi before inspiratory flow ensues. The inspiratory threshold load is greater in the supine position and may account for much of the disordered chest wall mechanics in obesity.^{132,142,147}

Airway and total respiratory system resistance are increased in obesity, with values usually twice as much as

those in non-obese individuals.^{145,148} Total respiratory system resistance is elevated primarily due to an increase in airway resistance related to breathing at low lung volumes.^{145,148} However, since airway resistance remains elevated even after normalizing for lung volume (e.g., specific airway conductance is reduced to 50% to 70% of normal), other unknown factors, in addition to breathing at low lung volumes, may account for some of the increase in resistance.^{148-150,150a} The normal FEV₁/FVC ratio suggests that the greatest resistance to airflow may be at the level of the small airways rather than the large airways. The transition from the upright to supine position may further increase airway resistance.¹⁴⁵ The increase in the intra-abdominal pressure when supine may further reduce FRC resulting in expiratory flow limitation during tidal breathing and orthopnea in severe obesity.^{147,151,152} The negative impact of the supine position on respiratory mechanics must be considered when evaluating obese patients for risks following general anesthesia.¹⁵³

The work of breathing is increased in both simple obesity and OHS.^{146,154,155} Three factors that contribute to the increase in work include increased elastic loads (reductions in compliance), threshold loads (increases in the pressure needed to initiate inspiration), and resistive loads (increases in pressure imposed by the airways).¹⁴³ The work of breathing can be up to 60% greater in simple obesity and as much as 250% higher in OHS.^{146,154,155} The increased work together with a reduced efficiency of breathing increases the oxygen cost of breathing fivefold in simple obesity and tenfold in OHS.¹⁴¹ The increased oxygen cost of breathing may place obese patients at risk for respiratory failure during states of increased ventilatory demands such as during inter-current illness.¹⁵⁵ To minimize the elastic load during inspiration and optimize the oxygen cost of breathing, obese patients adopt a rapid, shallow breathing pattern. This strategy is more pronounced in OHS than in SO.¹⁵⁶⁻¹⁵⁸ In subjects with SO, the respiratory rate during quiet breathing is about 40% higher than in normal-weight subjects with most of the lung volume change during tidal breathing accomplished by rib cage rather than by abdominal displacement.¹⁵⁸ In OHS, however, breathing frequency is 25% higher and V_T 25% lower than in simple obesity.^{157,159} The adverse effect of adopting a rapid shallow breathing pattern is increased dead space ventilation which may contribute to carbon dioxide retention.^{155,159}

Gas Exchange

In patients with simple obesity, the arterial PO₂ is usually normal or slightly reduced.¹⁶⁰ However, in patients with OHS or morbid obesity, the hypoxemia is more pronounced.^{135,136,160} In addition to hypoventilation, ventilation-perfusion mismatch and shunt due to premature airway closure widen the alveolar-arterial oxygen tension gradient and contribute to hypoxemia.^{160,161} The hypoxemia is worse in the supine position and in males.^{145,161,162} During exercise, oxygenation may improve due to enhanced ventilation of the lung bases.^{162,163} Weight loss will improve oxygenation by shifting FRC towards normal; an increase in FRC lessens the degree of airway closure during tidal breathing and improves arterial PO₂ roughly by 1 mm Hg for every 5 kg reduction in weight.¹⁶⁰ A practical corollary of hypoxemia and the increased metabolic rate in obesity is that,

during apnea, the arterial oxygen saturation may fall three times faster in obese individuals than in normal-weight subjects.¹⁶⁴

Control and Pattern of Breathing

Differences in the control of breathing may also explain why hypercapnia is found in some but not all obese individuals of similar BMI. In eucapnic obese individuals, central respiratory drive is intact. Respiratory drive, as measured by the P_{0.1}, ventilatory, or electromyographic responses to hypoxia or hypercapnia, is normal or even increased because of the elastic and threshold loads placed on the inspiratory muscles.^{141,147,165} If the elastic and threshold loads are lessened by weight loss, the compensatory increase in ventilatory drive decreases.^{166,167} In patients with OHS, however, respiratory drive is blunted and the P_{0.1}, ventilatory, or electromyographic response to hypoxia or hypercapnia is reduced.^{165,168} The exact mechanism underlying the attenuated ventilatory drive in OHS is unknown. Mechanical disadvantage in OHS does not adequately explain the hypercapnia as most patients with OHS can normalize arterial PCO₂ through volitional hyperventilation.¹⁶⁹ A genetic predisposition is unlikely because ventilatory drive is intact in first-degree relatives of patients with OHS.¹⁷⁰ Instead, in those with OHS, the central chemoreceptors may be “reset” because of chronic hypoxemia or hypercapnia or because of reduced leptin or leptin resistance. Leptin is a protein produced by adipose tissue that acts in the hypothalamus to decrease appetite, increase metabolic rate, and stimulate breathing. The development of leptin resistance or a relative leptin deficiency may contribute to diminished ventilatory responsiveness and hypercapnia in OHS.^{135,171} Because serum leptin levels are generally increased in obesity, both in SO and even more so in OHS, a central resistance to leptin has been proposed.^{171,172}

The increased respiratory drive in simple obesity may contribute to the sensation of dyspnea.^{163,167,173} However, dyspnea is also a frequent and disabling symptom in OHS and may be related to airways disease, or disordered respiratory mechanics (decreased compliance, increased airway resistance, or expiratory flow limitation).^{154,163,173-176} Finally, dyspnea may be due to cardiac disease, a frequent comorbid condition.

Respiratory Muscle Function

In patients with simple obesity, respiratory muscle strength is usually normal; in fact, strength may be maintained by the chronic threshold and elastic loads imposed on the inspiratory muscles.^{145,147,176} In patients with OHS, respiratory muscle strength is usually decreased, perhaps because of deconditioning or other factors related to chronic disease.^{135,176} In severely obese subjects, especially those with dyspnea or OHS, diaphragm function may be impaired, especially in the supine position.^{176,177} This may be related to increased intra-abdominal pressure and cranial displacement of the diaphragm.¹⁷⁷

Exercise Capacity

In absolute terms, exercise capacity in those with simple obesity, as measured by symptom-limited maximal oxygen uptake, is similar to that of lean individuals. When normalized to fat-free mass, however, maximal oxygen uptake is

lower in obese than in non-obese individuals.^{163,178} For a given rate of work, obese individuals require a greater $\dot{V}O_2$ and minute ventilation. Likewise, dyspnea scores at any submaximal work rate are higher in obese individuals, reflecting the higher ventilation and metabolic costs of obesity.^{163,178} Obese individuals may increase end-expiratory volume during exercise to attenuate expiratory flow limitation due to breathing at low lung volumes.¹⁶³ This breathing strategy may assist them in accommodating their higher metabolic demands. In support of this notion, at any given $\dot{V}O_2$ or minute ventilation, dyspnea scores are similar to those of non-obese individuals, suggesting that respiratory mechanical factors do not contribute significantly to respiratory discomfort.^{163,174}

TREATMENT

Weight loss is the optimal therapy but is not always attainable, and long-term weight loss maintenance is even more difficult.¹⁷⁹ Generally, weight loss programs emphasize diet, enhanced physical activity, and behavioral therapy as initial treatments in all obese individuals regardless of the severity of obesity. Bariatric surgery can produce not only a substantial weight loss but also long-term maintenance of weight loss.¹⁸⁰ It is indicated in obese individuals with a BMI of at least 40 kg/m² and in those with a BMI of at least 35 kg/m² with serious comorbidities.^{179,181} Weight loss in obese individuals is associated with improved ERV and FRC¹⁸²; however, there is no correlation between the magnitude of weight loss and the degree of improvement of lung volumes. Weight loss also may improve respiratory muscle performance,¹³⁷ resting gas exchange,¹⁸³ diffusion capacity,¹⁶⁰ dyspnea scores,^{167,184} sleep apnea,¹⁸⁴ 6-minute walk test¹⁸⁵ airway responsiveness,¹⁸⁶ and respiratory drive.¹⁶⁷ Overall, weight reduction appears to be the most effective solution to OHS, with bariatric surgery providing the best option for the various comorbid conditions related to extreme obesity, such as hypertension, hyperlipidemia, cardiac dysfunction, and type 2 diabetes.^{187,188}

Key Points

- Diseases that affect the chest wall, including obesity, primarily affect the respiratory system by reducing chest wall compliance. The degree to which the chest wall stiffens varies with the disease process. Individuals with kyphoscoliosis may have the greatest degree of chest wall stiffness whereas individuals with pectus excavatum or ankylosing spondylitis may have normal chest wall compliance.
- The lung is usually an “innocent bystander” in the sense that it is usually not primarily affected by a pathologic process. When restrictive chest wall disorders limit full inflation of the lung, microatelectasis

ensues which can lead to a reduction in lung compliance and impaired gas exchange.

- Of the chest wall disorders, flail chest is most likely to precipitate acute respiratory failure whereas kyphoscoliosis and severe obesity are most likely to lead to chronic ventilatory failure, pulmonary hypertension, and cor pulmonale. Coincident inspiratory muscle weakness in any of these disorders will further worsen restrictive pathophysiology and predispose to respiratory failure.
- Acute respiratory failure may complicate flail chest and can be treated with positive-pressure ventilation. In some patients with flail chest, surgical fixation of the flail segment may reduce the duration of mechanical ventilation and improve long-term pulmonary function.
- Chronic respiratory failure, which can be seen in kyphoscoliosis or with severe obesity, can be successfully managed with noninvasive nocturnal positive-pressure ventilation. This latter intervention has markedly improved morbidity and mortality in this group of individuals.

ACUTE VENTILATORY FAILURE DUE TO VASCULAR IMPAIRMENT

INTRODUCTION

Respiratory failure exists when the respiratory system cannot maintain gas exchange, causing dysfunction in other organs or threatening life. Such impairment primarily affects oxygenation, manifested by hypoxemia, or affects ventilation, manifested by hypercapnia and respiratory acidosis. This chapter deals with this latter circumstance, commonly called ventilatory failure.

Carbon dioxide (CO_2) tension in the arterial blood (PaCO_2) is a function of *alveolar ventilation* (\dot{V}_A) and CO_2 production ($\dot{V}\text{CO}_2$), according to the following relationship.

$$\text{PaCO}_2 = (\dot{V}\text{CO}_2 \times k) / \dot{V}_A \quad (1)$$

Total minute ventilation is the sum of both \dot{V}_A and dead space ventilation. Either a decrease in total minute ventilation or an increase in dead-space ventilation can thus

decrease \dot{V}_A . Any decrease in \dot{V}_A or increase in $\dot{V}\text{CO}_2$ relative to \dot{V}_A results in an increase in arterial PCO_2 . Because bicarbonate retention by the kidney in response to hypercapnia is slow, a sudden increase in arterial PCO_2 will not be buffered quickly by bicarbonate and thus will abruptly lower arterial pH. Ventilatory failure exists whenever arterial PCO_2 is substantially elevated, and acute ventilatory failure is present when the change from the patient's baseline state develops rapidly enough to produce a clinically important drop in arterial pH. Because patients with severe *chronic obstructive pulmonary disease* (COPD), chronic neuromuscular disease, and other disorders may already have hypercapnia at baseline, the presence of a component of acute (acute-on-chronic) ventilatory failure is determined not so much by the arterial PCO_2 value as by the presence of acidemia, typically to an arterial pH of less than 7.35. The presence of acute ventilatory failure cannot be

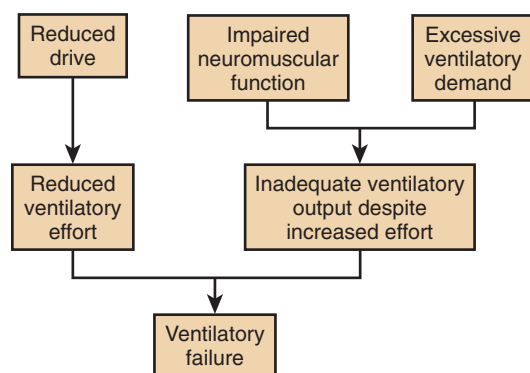

Figure 99-1 The physiologic mechanisms of acute ventilatory failure. The two major causes of acute ventilatory failure are either a reduced ventilatory effort or a reduced ventilatory output despite increased effort.

determined accurately by physical examination, pulse oximetry, exhaled CO_2 , or other noninvasive tests. Thus, making the diagnosis requires arterial blood gas analysis.¹

PATHOPHYSIOLOGY OF ACUTE VENTILATORY FAILURE

Alveolar ventilation becomes inadequate in relation to CO_2 production either because of a failure of the patient's ventilatory capability (pump failure) or ventilatory effort (drive failure)^{2,3} (Fig. 99-1). These two mechanisms are distinct in their clinical presentations. Patients with acute failure of the ventilatory pump are dyspneic and tachypneic with other signs of distress, whereas patients with failure of ventilatory drive are not short of breath and typically demonstrate bradypnea or apnea.

Although acute ventilatory failure is primarily a disorder of alveolar ventilation, hypoxemia is also usually present. Alveolar hypoventilation causes a proportional fall in *alveolar oxygen pressure* (PAO_2), according to the alveolar gas equation.

$$\text{PAO}_2 = \text{PIO}_2 - (\text{PaCO}_2 / R) \quad (2)$$

where arterial PCO_2 is assumed to be nearly the same as alveolar PCO_2 , PIO_2 is the inspired PO_2 (i.e., the inspired oxygen fraction multiplied by the difference of barometric pressure and 47 [water vapor pressure at body temperature]), and R is the respiratory exchange ratio. This relationship explains the fall in arterial PO_2 that accompanies alveolar hypoventilation, as shown in Figure 99-2.² Calculating alveolar PO_2 using Equation 2 permits determination of the *alveolar-arterial oxygen pressure difference* ($(A-a)\text{PO}_2$) (commonly but imprecisely called the “A-a gradient” and more precisely called the “A-a oxygen tension difference”). This calculation distinguishes between pure hypoventilation as an explanation for hypoxemia (in which case, $(A-a)\text{PO}_2$ is normal) and the presence of other mechanisms such as low *ventilation-perfusion* (\dot{V}/\dot{Q}) ratios and right-to-left shunt (in which case, $(A-a)\text{PO}_2$ is increased).

Finally, hypercapnia can be a feature of hypoxemic respiratory failure if the derangement in gas exchange is sufficiently severe. Both right-to-left shunt and low \dot{V}/\dot{Q} ratios are present in the *acute respiratory distress syndrome*

Figure 99-2 Relationship between arterial PO_2 and arterial PCO_2 . There is a reciprocal relationship between arterial oxygen pressure (PaO_2) and arterial carbon dioxide pressure (PaCO_2) as ventilation increases or decreases, assuming that the $(A-a)\text{PO}_2$ difference does not change and the respiratory exchange ratio is 0.8. (Redrawn from Pierson DJ, Kacmarek RM, editors: *Foundations of respiratory care*. New York, 1992, Churchill Livingstone, p 298.)

(ARDS) and can increase *dead space-to-tidal volume ratios* (V_D/V_T) as determined by the Bohr equation,⁴ thus impairing CO_2 elimination and contributing to hypercapnia.

Table 99-1 classifies the typical clinical presentations of acute ventilatory failure according to the site or type of defect and the physiologic mechanism or category of disorder responsible. Not every listed example is discussed in this chapter.

More than one mechanism may coexist in a given patient, producing a life-threatening condition even when the individual processes are only moderate in severity. For example, in decompensated obesity-hypoventilation syndrome, a patient whose underlying respiratory drive is reduced and whose obesity poses an increased elastic load on the ventilatory pump may develop acute-on-chronic ventilatory failure in the presence of a relatively modest increase in the work of breathing from an additional restrictive effect of cardiomegaly and pleural effusions.

ACUTE VENTILATORY FAILURE DUE TO INSUFFICIENT VENTILATORY DRIVE

CONGENITAL CAUSES

Congenital disorders that may be associated with diminished hypoxic or hypercapnic ventilatory drive include primary alveolar hypoventilation (or Ondine's Curse),⁵ Prader-Willi syndrome,^{6,7} hypogonadism treated with exogenous testosterone,⁸ and Arnold-Chiari malformation.⁹ These disorders contribute to the development of acute ventilatory failure through diminished ventilator drive, often in combination with other contributing mechanisms (such as acute infection), and are most often seen in pediatric settings.

ACQUIRED CAUSES

Decreased ventilatory drive is a frequent contributor to the development of chronic ventilatory insufficiency but is

Table 99-1 Clinical Classification of Ventilatory Failure by Site

Site of Defect	Mechanism or Type	Clinical Examples
Ventilatory drive	Congenital Acquired Combination	Primary alveolar ventilation (Ondine's Curse) Drug overdose (opioids, sedatives, alcohol); general anesthesia Cerebrovascular accident; neoplasm; carotid body resection Obesity-hypoventilation syndrome; myxedema
Neural transmission Spinal cord	Trauma Vascular Tumor Other Demyelinating	Cervical spinal cord injury Vascular accident Primary or metastatic Poliomyelitis; amyotrophic lateral sclerosis Acute idiopathic demyelinating polyneuropathy (Guillain-Barré syndrome)
Peripheral nerves Neuromuscular junction	Phrenic nerve lesion Pharmacologic Autoimmune Infectious/toxins	Trauma; cardiac surgery; neoplasm; idiopathic Neuromuscular blocking agents Myasthenia gravis Botulism, tetanus, tick paralysis
Ventilatory muscles	Congenital Autoimmune Acquired	Muscular dystrophy Polymyositis; dermatomyositis Hypophosphatemia; hypokalemia; hypomagnesemia; myxedema
Thoracic Vertebrae and rib cage Soft tissues	Decreased mobility Extrapulmonary restriction and decreased mobility	Kyphoscoliosis; tight casts or bandages; ankylosing spondylitis; flail chest Severe obesity
Pleura	Extrapulmonary restriction	Pneumothorax; pleural effusion; pleural thickening; malignancy
Airways Upper airways Lower airways	Obstruction Obstruction	Epiglottitis, foreign body, tumor, vocal cord paralysis, tracheomalacia COPD, acute severe asthma
Parenchyma	Increased dead space and very high \dot{V}/\dot{Q} Very low \dot{V}/\dot{Q} ; shunt	COPD Severe ARDS
Pulmonary circulation	General hypoperfusion Localized hypoperfusion	Hypovolemic or cardiogenic shock, CPR, pulmonary hyperinflation (intrinsic PEEP) Pulmonary thromboembolism; venous air embolism
Other	Increased CO ₂ production (inflammation; hypermetabolism; muscle activity) Exogenous CO ₂ inhalation	Fever; sepsis; burns; severe trauma; shivering; tetany; seizures; malignant hyperthermia Laboratory or industrial accident; therapeutic use; rebreathing

ARDS, acute respiratory distress syndrome; CO₂, carbon dioxide; COPD, chronic obstructive pulmonary disease; CPR, cardiopulmonary resuscitation; PEEP, positive end-expiratory pressure; \dot{V}/\dot{Q} , ventilation-perfusion ratio.

typically not the sole mechanism for acute ventilatory failure, except for those patients presenting with drug-induced suppression.

PHARMACOLOGIC CAUSES

Depression of the drive to breathe by drugs is by far the most common circumstance of this form of acute ventilatory failure. The opioids are potent depressors of both hypoxic and hypercapnic ventilatory drive; however, any sedative, hypnotic, or anxiolytic agent causes respiratory depression if administered in sufficient quantity.¹⁰ Propofol, in particular, is a potent respiratory depressant used commonly for sedation during procedures or during mechanical ventilation and must be dosed with caution in patients breathing spontaneously.¹¹ Respiratory depression resolves as the drug is cleared from the body or is pharmacologically antagonized, as signaled by the return of spontaneous breathing efforts. Because the central nervous system effects of some agents may wax and wane due to the enterohepatic circulation, lipid storage, or other mechanisms, patients should be observed until it is clear that the ventilatory drive has been reestablished before they are weaned from ventilatory support. In the case of drug overdoses and other poisoning,

identifying the specific agent or agents involved and the use of any specific therapies available, such as antidotes or dialysis, is important to expedite the weaning process from ventilatory support.¹⁰ Patients who fail to wean from mechanical ventilation because of inadequate drive from depressant drugs breathe slowly or not at all when ventilatory support is briefly discontinued. The much more common reason for difficulty weaning after drug overdose is that other mechanisms (e.g., aspiration pneumonia or sepsis) intervene. In these circumstances, with a return of respiratory drive, patients become tachypneic and manifest signs of respiratory distress when ventilatory support is discontinued.¹²

OTHER ACQUIRED CAUSES

Myxedema^{13,14} may present with hypercapnia related to acquired depression of ventilatory drive, and hypothyroidism may be a cofactor when patients present with worsening hypercapnia. Thyroid function testing should be done routinely in patients with new or worsening hypercapnia, especially when a clear physiologic explanation is inapparent. Patients with underlying abnormalities of ventilatory drive who develop respiratory infections, congestive heart failure, or other acute illnesses are more likely to develop

acute ventilatory failure compared with individuals without such defects.

The obesity-hypoventilation syndrome, discussed in Chapter 89, is characterized by blunted responses to hypoxia and hypercapnia¹⁵ and is one disorder in which patients may first present in acute ventilatory failure. Typically, such patients have a history of recent weight gain and are found to be markedly fluid-overloaded, with features of cor pulmonale. The increased work of breathing from decreased chest wall compliance, cardiomegaly, and often large pleural effusions, as well as worsening hypoxemia, all contribute to respiratory muscle fatigue and the development of severe hypercapnia and respiratory acidosis. Hypoventilation and acute ventilatory failure related to obesity are more common among hospitalized patients with severe obesity than has previously been reported.^{16,17} As the prevalence of obesity increases, ventilatory failure from decompensation of the obesity-hypoventilation syndrome is likely to be encountered more frequently.

Acute stroke is another setting in which disordered ventilatory drive may contribute to acute ventilatory failure, even though other processes are usually present, especially the inability to protect the lower airway and to clear respiratory tract secretions.^{18,19} The prognosis of patients with ischemic and hemorrhagic strokes who require intubation and mechanical ventilation is poor both in the short and long term, with a survival rate of 50% at 30 days and 30% after 1 year.^{18,20,21} Prognosis is especially unfavorable after basilar artery occlusion due not only to depressed respiratory drive but also to the swallowing impairment and problems with secretion clearance seen with brain stem injury.²²

Although data are not encouraging and the mortality rate is still high, American Heart Association guidelines recommend mechanical ventilation for patients with acute stroke if needed (Level IC).²³ Of course, this necessitates an ethical discussion with the patient and/or family to determine the patient's wishes regarding aggressive support (see Chapter 104).

PRINCIPLES OF MANAGEMENT

Because the underlying physiologic defect is inadequate ventilatory drive despite a presumably normal ventilatory pump, management focuses on restoring normal alveolar ventilation. Although *noninvasive ventilation* (NIV) is being applied in an increasing number of clinical settings to augment alveolar ventilation, its utility lies mainly in maintaining respiration in patients with failure of the ventilatory pump, whereas endotracheal intubation is generally necessary following acute failure of respiratory drive. NIV can be quite effective in treating chronic congenital or acquired central hypoventilation in outpatients, but in the setting of acute loss of respiratory drive, invasive mechanical ventilation restores alveolar ventilation more rapidly and reliably and is more effective for airway protection and secretion clearance than is NIV.

Because of the patient's impaired ventilatory drive, a ventilator mode that provides full support, such as volume-targeted assist-control ventilation, should initially be chosen. In the absence of acute lung injury or severe airflow obstruction, ventilator settings should be chosen to aim for values of arterial pH and arterial PCO₂ in the normal

range, and supplemental oxygen should be supplied (with *positive end-expiratory pressure* [PEEP] if necessary) to maintain normal arterial PO₂. Unless there are serious coexisting pulmonary conditions, weaning should be carried out as soon as there is evidence that ventilatory drive is restored (see Chapter 101). Extubation is probably safe if the patient has a spontaneous cough, does not require frequent suctioning, and is judged to be able to protect the airway, even if alertness remains impaired.²⁴

ACUTE VENTILATORY FAILURE DUE TO NEURAL TRANSMISSION IMPAIRMENT (see Chapter 97)

CERVICAL SPINAL CORD INJURY

Injury to the upper cervical spinal cord may interrupt transmission of the stimulus to breathe from the respiratory centers in the brain stem to the diaphragm and other ventilatory muscles, depending on the injury level. Because the phrenic nerve roots that supply the diaphragm arise from spinal segments C3 to C5, patients with acute injury at this level or above usually require ventilatory assistance. Patients with C1–C2 spinal injury levels are permanently ventilator dependent, whereas those with C3–C4 injuries may eventually achieve at least partial ventilator independence. Lesions below C4 are usually compatible with unassisted ventilation unless there are complicating processes such as intrinsic lung disease or impaired mental status.

Adverse physiologic effects can happen within the first days or weeks after the injury, including loss of lung volumes and inability to take deep breaths (which predisposes to atelectasis), inability to cough normally (which predisposes to the development of pneumonia and complicates its management), and impaired hypoxic pulmonary vasoconstriction (which predisposes to severe and often refractory hypoxemia after atelectasis or pneumonia).²⁵ These physiologic effects depend on the level of injury, being more frequent with lesions above C4, and on the degree of injury, being more frequent with complete, than with incomplete, lesions.²⁶

The short-term prognosis of spinal cord lesions is generally related to the level of the injury,²⁵ even though some retrospective studies have shown that both mortality^{27,28} and *intensive care unit* (ICU) length of stay²⁵ are more strongly influenced by the development of pneumonia and other respiratory complications than by the specific cord injury level.

Although there are reports of initial management of patients with high cervical spinal cord injury (C3–4 or higher) with NIV,²⁹ great expertise is required to avoid aspiration and other complications. Decisions about NIV should be made on a case-by-case basis²⁶; in most centers, invasive ventilatory support is preferable, at least initially. Phrenic nerve^{30–32} or diaphragm pacing,³³ permitting extubation or removal of the tracheostomy tube (decannulation), has also been reported in the later period following injury. The eventual ability to wean from ventilatory support and to undergo decannulation from tracheostomy are major determinants not only of survival but also of quality of life for patients with cervical spinal cord injury.^{25,27}

MOTOR NEURON DISEASE

Amyotrophic lateral sclerosis (ALS) and other motor neuron diseases demonstrate a variable but progressive weakness of the bulbar and ventilatory muscles. This progression determines the course of ventilatory failure and pulmonary complications, which represent the most common cause of death in these patients.^{34,35} Typically, ventilatory muscle weakness develops gradually after the diagnosis is already well established; therefore repeated assessments during outpatient evaluation are useful to monitor the progression of ventilatory muscle impairment.³⁴⁻³⁸ This permits intervention with NIV or, less often, tracheostomy before the onset of acute ventilatory failure. However, some cases present with acute ventilatory failure as the initial manifestation of the disease.³⁹

Elective initiation of noninvasive ventilation is becoming a standard of care in motor neuron disease patients with progressive ventilatory impairment because it improves both quality of life and survival rate^{37,38,40} in patients without significant bulbar involvement. NIV has been successful not only in the chronic, slowly progressive setting, but also in acute ventilatory failure complicating ALS.⁴¹ However, bulbar weakness and a high risk of aspiration make invasive mechanical ventilation a preferred choice for ALS patients with acute ventilator failure, at least initially. With appropriate counseling about end-of-life planning, only a small proportion of patients with ALS receive invasive mechanical ventilation, and presentation to an emergency department with acute ventilatory failure should be unusual.⁴²

INJURY OR DISEASE AFFECTING THE PHRENIC NERVE

Loss of diaphragm function leading to ventilatory failure is often due to spinal cord injury, immunologic diseases (such as Guillain-Barré syndrome or multiple sclerosis), or neuropathy (ALS, Charcot Marie Tooth). Unilateral paralysis of the diaphragm leading to ventilatory failure may be a result of phrenic nerve injury or disease. Its presentation ranges from an incidentally discovered radiographic abnormality without clinical impact to acute ventilatory failure requiring long-term mechanical ventilation, although the latter is quite unusual and generally due to multiple factors.^{31,43} In the past, unilateral diaphragmatic palsy following phrenic nerve injury was most often caused by cold cardioplegia during open-heart surgery or direct injury during internal mammary artery harvesting.⁴⁴ Since routine use of insulation for the phrenic nerves during cardiac surgery, this complication is now rare, but unilateral or bilateral phrenic nerve palsies are still seen as a consequence of direct invasion by neoplasm, infectious diseases (such as herpes zoster and Lyme disease), metabolic peripheral neuropathy (diabetes or porphyria), and radiotherapy.⁴⁵ Although acute ventilatory failure as a consequence of bilateral diaphragmatic paralysis is unusual, these patients are much more symptomatic than those with unilateral paralysis and usually have severe orthopnea.

IMMUNOLOGIC NEUROPATHIES

Guillain-Barré syndrome, now known as *acute idiopathic demyelinating polyneuropathy* (AIDP), is an autoimmune

polyneuropathy that accounts, together with myasthenia gravis, for the majority of admissions for ventilatory failure due to neuromuscular impairment.⁴⁶⁻⁵¹ Therapy with plasma exchange and intravenous immunoglobulin improves outcomes in AIDP, although 2% to 10% still die, and up to 20% of individuals who survive remain seriously disabled.⁵² Theoretically, death should be preventable in the vast majority of patients with this disease because mortality is primarily from potentially avoidable respiratory complications (see the discussion in Chapter 97). It remains unclear whether the need for mechanical ventilation can be predicted before the onset of frank ventilatory failure in this condition.⁵³

NEUROMUSCULAR JUNCTION IMPAIRMENT

Immunologic Disease

Myasthenia gravis is less common than AIDP as a cause of acute ventilatory failure, although up to 15% to 20% of myasthenic patients experience a crisis during their lifetime. These events usually happen in patients with an established diagnosis of myasthenia gravis. With adequate therapy (plasmapheresis and intravenous immunoglobulin) and respiratory support through noninvasive or invasive mechanical ventilation, the mortality rate is 5% to 10%.^{54,55} Isolated ventilatory muscle weakness requiring mechanical ventilation has been reported as the initial manifestation of the disorder.⁴⁶

Infectious Disease

Botulism remains an infrequent but important cause of acute ventilatory failure worldwide. In western countries, the incidence of ventilator failure due to food-borne illness has been unusual but steady in recent decades, with about 23 cases/year in the United States. On the other hand, due to subcutaneous injection of black-tar heroin, the incidence of wound botulism has been rising since the 1990s among injectable drug users.⁵⁶⁻⁵⁸ The vast majority of patients with both forms of botulism manifest respiratory symptoms and up to 75% of individuals develop clinically significant respiratory failure due to progressive descending flaccid paralysis, requiring mechanical ventilation, which is usually more prolonged in wound botulism patients.^{59,60} Recovery may likewise be prolonged, with residual ventilatory muscle weakness detectable as long as 2 years after presentation.⁶¹

Myopathies

Primary myopathies due to muscular dystrophies or other congenital myopathies are an uncommon cause of acute respiratory failure in most acute care hospitals but are more common in the pediatric setting. These patients usually develop ventilatory failure gradually and are begun on NIV in an outpatient setting. When they present with acute ventilator failure, it is usually in the setting of a precipitating factor such as pneumonia or bronchitis that causes problems with secretion retention. In such an event, they should be placed in an intensive care unit and treated with an aggressive regimen to assist with secretion clearance.⁶² Endotracheal intubation may be necessary to control secretions with weaning to NIV once the acute crisis subsides. Dermatomyositis may also cause respiratory muscle

weakness severe enough to lead to acute ventilatory failure,^{63,64} although not as an initial manifestation in the absence of other typical symptoms and signs of this condition. In these reported cases, ventilatory function recovered as the disease was brought under control with immunosuppressive therapy.

Pharmacologic Causes

Neuromuscular blocking drugs are sometimes administered to ventilated patients, in conjunction with sedation, to facilitate mechanical ventilation, reduce oxygen consumption, or control intracranial pressure. The clinical kinetics of these agents have been determined mainly in the context of short-term general anesthesia, and their effects on ventilatory muscle function in critically ill patients are much more variable. For example, most neuromuscular blocking drugs are cleared more slowly in the presence of hepatic or renal insufficiency. This is particularly true for pancuronium and vecuronium; the effects of these drugs can last days or even weeks in the presence of renal failure.⁶⁵ In contrast, atracurium and cisatracurium are metabolized in plasma and do not depend on renal or hepatic function for clearance; thus, they are not associated with prolonged muscle weakness as a result of delayed clearance.⁶⁶

Train-of-four stimulation can be used to monitor the depth of neuromuscular blockade, avoiding excessive paralysis and reducing the quantity of drug used, as well as the recovery time of neuromuscular function in critically ill patients.⁶⁷ Although these benefits may not be seen when atracurium and cisatracurium are used,⁶⁸ train-of-four testing is sufficiently simple and inexpensive to perform that many experts believe it should be employed routinely.⁶⁹ Minimizing the use of neuromuscular blocking drugs in ventilator management and using train-of-four stimulation to monitor the degree of muscle relaxation, as well as employing daily interruptions of paralysis, may reduce the incidence of prolonged paralysis.⁷⁰

NEUROMUSCULAR WEAKNESS ASSOCIATED WITH CRITICAL ILLNESS

Neuromuscular dysfunction associated with critical illness commonly contributes to the subsequent inability to wean such patients from mechanical ventilation.⁶⁶ Several forms of critical illness-associated neuromuscular dysfunction are recognized.

Intensive Care Unit–Acquired Weakness

Unexpected acute weakness and prolonged ventilatory failure were first reported in patients with status asthmaticus treated with corticosteroids and neuromuscular blocking drugs.^{71,72} Subsequently, a similar syndrome was recognized in other groups of ICU patients, especially those with sepsis and systemic inflammation, even without corticosteroid administration or therapeutic paralysis.⁶⁶ Either muscle or nerve abnormalities can predominate, leading to a confusing array of diagnostic terms, such as “critical illness myopathy,” “critical illness polyneuropathy,” “post-paralytic myopathy,” “ICU-acquired paresis,” “acute quadriplegic myopathy,” and the preferred term, *ICU-acquired weakness*.

The pathophysiology of ICU-acquired weakness is poorly understood but may involve elements of disuse and active muscle catabolism sparked by systemic inflammation. Electromyography reveals reduced compound muscle action potentials on motor nerve stimulation (with normal conduction velocity); increased action potential duration; and spontaneous electrical activity on muscle needle recording (e.g., fibrillation potentials, positive sharp waves).⁷³ Biopsy findings may include primary axonal degeneration, type II muscle fiber atrophy, thick filament (myosin) loss, and (occasionally) necrotizing myopathy.

One quarter to one half of all patients who require more than 7 days of ICU care and the majority of patients who develop the systemic inflammatory response syndrome can be shown by neurophysiologic testing to have ICU-acquired weakness.⁶⁶ These neurophysiologic abnormalities arise early, accumulate during the course of illness, and usually affect both nerves and muscles.⁷⁴ Prospective studies have shown that about one third of critically ill patients exhibit weakness on clinical evaluation.^{66,75} The typical patient exhibits symmetrical extremity weakness in which proximal function is more impaired than distal function and the facial muscles are spared. Clinically, this disorder can produce severe neuromuscular weakness, often affects the respiratory muscles, and may prolong the need for ventilatory support.^{75,76} This syndrome should be suspected in patients who are weak (*Medical Research Council* score < 48⁷⁵) in the context of critical illness, have the typical clinical examination, and in whom no better alternative cause for weakness can be identified. Handgrip strength may serve as a simple test to identify ICU-acquired weakness.⁷⁷ Nerve conduction studies, electromyography, and muscle biopsy generally are not necessary, but their role in diagnosis remains an area of active investigation. The prognosis for recovery of strength is variable, with many patients improving rapidly over days to weeks while others remain weak for many months or longer. The incidence of ICU-acquired weakness may be reduced by intensive insulin therapy,^{76,78,79} avoiding neuromuscular blocking drugs and corticosteroids where possible, and possibly by early mobilization.^{80,80a} Because ICU-acquired weakness is so strongly associated with severity of illness, length of ICU stay, and the presence of multiple organ system dysfunction, prevention focuses on scrupulous attention to good general ICU care and avoidance of sepsis.⁶⁶

Ventilator-Induced Diaphragmatic Dysfunction

Many critically ill patients develop muscle weakness that impedes functional recovery and is associated with prolonged mechanical ventilation. Some component of this represents ICU-acquired weakness,⁸¹ but mechanical ventilation itself (without systemic inflammation) can induce respiratory muscle weakness.⁸²⁻⁸⁴ The lack of neural stimulation or associated contraction plays a role in the evolution of weakness because measures to keep muscles contracting can ameliorate weakness. The diaphragm, the muscle most responsible for sustaining the work of breathing, may be even more sensitive than other skeletal muscles to the effects of critical illness. In animal models, the diaphragm weakens during the first 1 to 3 days of mechanical ventilation. Using phrenic nerve stimulation, one study demonstrated weakness by measuring a reduction in maximal

transdiaphragmatic pressure in a group of continuously ventilated patients in comparison with findings in normal volunteers.⁸⁵ As in studies of peripheral skeletal muscle, stimulating the diaphragm attenuates the loss of strength.⁸⁶ This suggests that partial rather than full ventilatory support may serve to maintain diaphragmatic strength, potentially reducing time on the ventilator.⁸⁶

ASSESSMENT OF NEED FOR MECHANICAL VENTILATION IN NEUROMUSCULAR WEAKNESS

Respiratory muscle weakness can be suspected when there is obvious peripheral muscle weakness, but neuromuscular abnormalities may not always be evident. Respiratory muscle weakness should also be suspected when dyspnea is out of proportion to radiographic and respiratory mechanical abnormalities seen during mechanical ventilation. Orthopnea raises the possibility of diaphragmatic weakness or paralysis. Further, suspicion is raised when maximal inspiratory pressure is reduced or, in some instances, when ultrasound examination of the diaphragms is abnormal.

Early clinical indicators of the need for mechanical ventilation in patients with neuromuscular weakness remain controversial. In addition to subjective assessments of symptoms of dyspnea and respiratory distress, objective assessments of vital capacity and maximum inspiratory and expiratory pressures have been used to evaluate ventilatory muscle capability.

In AIDP, rapid disease progression, bulbar and bilateral facial weakness, and dysautonomia are highly correlated with the need for intubation and mechanical ventilation. Moreover, a reduced vital capacity (<20 mL/kg), maximum inspiratory pressure (less negative than -30 cm H₂O), and maximum expiratory pressure (<40 cm H₂O) are associated with the need for intubation.⁵⁰ However, no prospective randomized studies have assessed these variables, and predictors of the need for intubation may merely reflect the criteria in current use to determine when a patient should be intubated.

One study on AIDP reported an association between electrophysiologic evidence of demyelination and the need for intubation and mechanical ventilation.⁸⁷ Another study on 44 AIDP patients who required mechanical ventilation showed greater cranial nerve involvement and *immunoglobulin G* (IgG) anti-GQ1b antibody levels than 87 AIDP patients not requiring intubation.⁸⁸ These could also be markers of greater disease severity, thus explaining the higher intubation rates.

In *myasthenia gravis* (MG), the criteria to predict the need for intubation are not as reliable as for AIDP, mostly due to the fluctuating nature of MG.⁸⁹ Nonetheless, serial assessments of vital capacity and the use of the same predictors as for AIDP are still recommended in MG as long as the patient is monitored closely in an ICU and caregivers are prepared for emergent intubation if necessary.^{90,91}

In ALS, as previously noted, serial ventilatory muscle assessments during outpatient management are required for the timely initiation of NIV to avoid respiratory crises and the need for emergency intubation. Evaluation of clinical signs of respiratory muscle weakness (such as use of accessory muscles and paradoxical or diminished excursion of the abdomen) and symptoms of diaphragm weak-

ness (such as orthopnea) are important to assess. We recommend serial measurement of pulmonary function tests, nocturnal oximetry, and sniff inspiratory pressure as an index of diaphragm strength. Recommendations for starting NIV in ALS patients vary widely from FVC less than 80% predicted, with the idea that deterioration in respiratory muscle function can be slowed, to less than 50% predicted in the United States as per the threshold for Medicare reimbursement for NIV.⁹²⁻⁹⁴ The authors believe that data are insufficient to make firm recommendations on any specific FVC threshold for NIV initiation but that, in association with pulmonary dysfunction, NIV should be started when patients develop symptoms that are likely to respond to NIV. For example, dyspnea at rest or orthopnea can respond to NIV, as can symptoms attributable to poor sleep, such as daytime fatigue, hypersomnolence, or morning headaches.

Although the optimal means for monitoring respiratory muscle function remain uncertain, it is clear that initiation of NIV or, if that fails, intubation and mechanical ventilation (if patients desire it) should be undertaken before the development of severe respiratory acidosis or respiratory arrest. For this reason, patients with acute neuromuscular disease who show signs of pulmonary compromise should be monitored in an ICU. Although the rate of progression may fluctuate, serial measurements of vital capacity and maximal inspiratory pressure along with repeated physical examinations focusing on bulbar function and ability to cough are advisable to avoid emergent intubations (Fig. 99-3).⁹⁵

Figure 99-3 The sequence leading from ventilatory pump failure to respiratory arrest. Individual patients proceed through the steps shown at variable rates and may skip one or more stages. However, except for sudden events affecting the central nervous system or the administration of paralyzing drugs, respiratory arrest does not present abruptly without preceding physical manifestations. (Adapted in part from Cohen CA, Zagelbaum G, Gross D, et al: Clinical manifestations of inspiratory muscle fatigue. *Am J Med* 73:308–316, 1982.)

PRINCIPLES OF VENTILATOR MANAGEMENT

Patients with acute ventilatory failure due to neuromuscular disease usually have normal underlying lung parenchyma. Although NIV is often used successfully in these patients, significant bulbar involvement is associated with a high likelihood of NIV failure and patients with these deficits should be intubated if the goal is prolongation of life. Intubated patients are usually supported with volume-targeted ventilators using tidal volumes of 6 to 8 mL/kg, rates slightly below spontaneous, and 5 to 10 cm H₂O PEEP to prevent atelectasis. These targets can also be achieved using portable pressure-limited ventilators with the pressure difference between inspiratory and expiratory pressure adjusted to achieve similar tidal volumes (pressure difference usually at least 8 to 10 cm H₂O) while avoiding respiratory alkalosis. In patients requiring continuous ventilatory assistance, settings should aim not only to maintain gas exchange but also comfort, considering that there is no convincing evidence that “exercising” respiratory muscles in neuromuscular disease speeds recovery. Some advocate a new protocol using prophylactic NIV and mechanical cough assistance to facilitate extubation and avert the need for reintubation in patients with neuromuscular disease who are weaning from invasive mechanical ventilation.^{62,96}

ACUTE VENTILATORY FAILURE DUE TO CHEST WALL DEFECTS

(see Chapter 98)

Many restrictive diseases of the lungs or chest wall progress insidiously over months or years. Critical illness may represent the natural history of the underlying condition but may also signal an acutely superimposed, potentially reversible crisis such as infection, pneumothorax, or thromboembolism.

CHEST WALL SKELETAL ABNORMALITIES

Thoracic restriction and ventilatory muscle dysfunction due to severe kyphoscoliosis typically lead to gradually progressive ventilatory insufficiency. Such patients can present with acute or acute-on-chronic ventilatory failure and require intensive care. Physiologic studies have shown that both lung and chest wall mechanics are impaired during acute respiratory failure in patients with kyphoscoliosis.⁹⁷ Chest trauma, especially when leading to flail chest due to rib fractures, may also cause the development of acute hypercapnic respiratory failure. In either case, the ventilator pump fails because of inability to sustain ventilatory work due to abnormalities that compromise ventilatory function, such as increased chest wall stiffness in kyphoscoliosis and decreased ventilator efficiency due to paradoxical chest wall motion and pain in flail chest.

PLEURAL DISEASE

Primary disease of the pleura, such as asbestos-related diffuse pleural thickening or postinflammatory fibrothorax,

could potentially present in a similar way as skeletal deformities, but dyspnea and hyperventilation are more common with these chronic pleural diseases. Respiratory acidosis develops late in the course of the disorder unless ventilatory drive is depressed or there is concomitant lung involvement. Pleural effusion or pneumothorax can likewise precipitate acute ventilatory failure, usually in the presence of underlying obstructive or restrictive pulmonary parenchymal disease.

PRINCIPLES OF MANAGEMENT

Long-term NIV appears to be beneficial in selected patients with kyphoscoliosis and other chest wall diseases⁹⁸ and has been reported to be successful in acute-on-chronic ventilatory failure.⁹⁹⁻¹⁰² Some recent studies report that NIV reduces the need for intubation and leads to a shortened hospital stay in patients with chest trauma.^{103,104}

Parenchymal Lung Disease

Idiopathic pulmonary fibrosis and other pulmonary parenchymal restrictive diseases are usually associated with hyperventilation rather than hypoventilation. However, acute ventilatory failure can arise in the late stages of these conditions, either as a manifestation of the primary disease process^{105,106} or, more often, in conjunction with pneumonia, surgery, or other intercurrent illness.¹⁰⁷⁻¹⁰⁹ Physiologic assessment has demonstrated marked increases in lung stiffness and airway resistance in patients with end-stage idiopathic pulmonary fibrosis requiring mechanical ventilation,¹⁰⁹ explaining the development of hypercapnia and acute ventilatory failure.

Several case series have documented the poor prognosis of patients who present with acute respiratory failure in the setting of advanced interstitial fibrosis.^{106,108,109} In one retrospective report, all 14 consecutive patients with acute respiratory failure and idiopathic pulmonary fibrosis admitted to the ICU died despite aggressive ventilatory support.¹⁰⁷ In another report of 23 similar patients, 22 patients died; the single survivor received a lung transplant shortly after admission.¹⁰⁸ In a third series of 19 patients with idiopathic pulmonary fibrosis and AREF, 13 died.¹⁰⁹ Outcomes appear equally poor regardless of whether ventilation is invasive or noninvasive.¹¹⁰

Principles of Ventilator Management

Due to increased lung stiffness, NIV for restrictive disease usually requires higher airway pressures than are used for COPD. Thus, avoiding gastric insufflation and air leaks around the mask is more challenging. Furthermore, considering that a superimposed condition such as a respiratory infection often precipitates the acute bout of respiratory failure, accompanied by increased work of breathing and secretion retention, invasive ventilatory support is often warranted. The best way to ventilate patients with acute respiratory failure in the setting of underlying restrictive thoracic or lung disease has not been determined by clinical trials. The potential for hemodynamic compromise, barotrauma, and ventilator-induced lung injury with the use of high pressures and the physiologic similarity to ARDS in patients with deteriorating pulmonary fibrosis make it reasonable to apply similar lung-protective ventilator strategies

and management targets (see Chapter 101). Low tidal volumes (e.g., 6 mL/kg predicted body weight) should be applied, attempting to keep the end-inspiratory plateau pressure below 30 cm H₂O if possible. Patients with restrictive lung disease typically breathe rapidly and shallowly, so tachypnea may not be avoidable during the weaning process and should not be used as the sole reason for delaying extubation if gas exchange and other assessments are acceptable.

ACUTE VENTILATORY FAILURE DUE TO AIRWAY OBSTRUCTION

UPPER AIRWAY OBSTRUCTION

Upper airway obstruction is an occasional cause of acute ventilatory failure. The onset can be precipitous, as with occlusion of the glottis by an aspirated foreign body (i.e., “café coronary”) or a swollen and edematous epiglottis due to acute epiglottitis.¹¹¹ The onset can also be insidious, progressing over months, as with a tracheal tumor. The severity and length of narrowing and air flow determine the airway resistance and thus the additional work of breathing imposed by the obstruction. Gradually progressive upper airway narrowing may be well tolerated, at least while breathing at rest, until a critical limit is reached, often when the airway diameter drops to the range of 5 to 6 mm.

The location and variability of the narrowing are also important in determining the clinical manifestations. Extrathoracic variable upper airway narrowing affects mainly inspiratory flow because the negative intraluminal pressure exacerbates the narrowing during inspiration. During expiration, the positive intraluminal pressure widens extrathoracic airways. Vocal cord paralysis is an excellent example of a variable extrathoracic upper airway obstruction, producing stridor and severe airway obstruction during inspiration but no significant obstruction during expiration. The opposite pertains to variable intrathoracic obstructions, with narrowing becoming less severe during inspiration because pressure gradients favor airway widening. During expiration, the airways narrow and the severity of the obstruction worsens. Tracheomalacia can cause variable intrathoracic airway obstruction. Fixed obstructions affect both inspiration and expiration regardless of their location.

Upper airway obstruction causes ventilatory failure by increasing airway resistance to the point where respiratory muscles can no longer sustain minute volume at a level adequate to maintain CO₂ homeostasis. Negative-pressure pulmonary edema can also contribute to the gas-exchange impairment.¹¹² Ideally, the therapeutic aim is to relieve the obstruction. This may be achieved by removal of a foreign body, laser therapy of an endotracheal tumor, placement of a stent in an area of tracheomalacia or stenosis, or tracheostomy to bypass an area of obstruction. Inhalation of heliox (to reduce airway resistance), *continuous positive airway pressure* (CPAP), or noninvasive ventilation using pressure support and PEEP can help to reduce the work of breathing and avoid intubation in patients who have reversible causes of their upper airway obstruction, such as

postextubation stridor, or who are awaiting tracheostomy or surgical repair of an obstruction. However, these temporizing measures require close monitoring with the recognition that the patient can deteriorate abruptly.

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

COPD is the third leading cause of death among adults aged 65 to 84 in the United States, being the primary contributor to mortality caused by lower respiratory disease, and poses enormous costs to the U.S. health care system, mostly due to hospitalization.¹¹³ The vast majority of hospitalizations are due to acute exacerbations of COPD, but other causes such as acute pneumonia, congestive heart failure, pulmonary embolism, and pneumothorax may contribute to the deterioration.

PATHOPHYSIOLOGY

Hyperinflation associated with severe COPD places the respiratory muscles at a mechanical disadvantage (Fig. 99-4). The loss of elastic structures is responsible for an increase in lung compliance leading to hyperinflation (with an increase in total lung capacity and functional residual capacity) and the collapse of small airways during expiration that contributes to an increase of residual volume, often referred to as “air trapping.” The flattening of the diaphragm increases the radius of curvature, which, according to the Law of Laplace, also increases muscle tension and impedance to blood flow. In addition, ventilatory efficiency is reduced because the shortened diaphragm operates at a disadvantageous position on its length-tension curve and the horizontal orientation of the flattened diaphragm causes the lower rib cage to move paradoxically during inhalation, inward rather than outward (“Hoover sign”).

Figure 99-4 Schema depicting the chest wall configuration at functional residual capacity of a normal individual (left) and a patient with severe COPD (right). The COPD patient has a flattened diaphragm, which increases its radius of curvature and increases the tension for a given pressure. The COPD patient's ribs are horizontal, and the zone of apposition between the diaphragm and chest wall is reduced, greatly reducing the diaphragm's efficiency in expanding the chest wall. Also, intrinsic positive end-expiratory pressure (auto PEEP) poses an inspiratory load, adding further to the inspiratory work. Exhalation is slowed by airway collapse and the loss of elastic recoil. (Redrawn from Hill NS: Current concepts in mechanical ventilation for chronic obstructive pulmonary disease. *Semin Respir Crit Care Med* 20:375–395, 1999.)

The hyperinflation and impairment in diaphragm function necessitate the recruitment of accessory muscles to maintain ventilation at higher lung volumes, contributing to the already increased oxygen cost of breathing. Finally, the collapse of small airways predisposes to incomplete emptying and positive intrathoracic pressure at end-expiration (intrinsic or auto-PEEP). Auto-PEEP poses an inspiratory threshold load requiring that inspiratory muscles lower the elevated alveolar pressure to subatmospheric in order to initiate airflow for the next breath.^{114,115}

During an exacerbation of COPD, the combination of airway swelling, secretions, and bronchospasm caused by acute inflammation increases airway resistance, further worsening the expiratory flow-limitation and increasing end-expiratory lung volume. As depicted in Figure 99-5, COPD patients adapt by attempting to maintain airflow by breathing at even higher lung volumes. In addition, they adopt a rapid, shallow breathing pattern that further limits the time available for expiration, aggravating intrinsic PEEP and adding further to the work of breathing. The diaphragm flattens more and develops increased tension, further impeding diaphragmatic blood flow. The resulting limitation in substrate delivery to muscle is aggravated by progressive hypoxemia, caused by worsening hypoventilation and \dot{V}/\dot{Q} imbalance related to secretion retention. Thus, as the demand for breathing increases, the capacity to supply breathing work diminishes. As respiratory drive increases in a futile attempt to reverse the worsening alveolar

hypoventilation, muscular performance deteriorates and the diaphragm fatigues.¹¹⁶ A vicious cycle ensues, leading inexorably to worsening respiratory muscle fatigue, ventilatory failure, and death unless therapeutic interventions interrupt the cycle.

Clinical Assessment

Patients with exacerbations of COPD must be carefully evaluated to identify those at risk of developing respiratory failure and to exclude other causes of respiratory failure. History and physical examination are useful. Although the Borg or visual analogue scales help gauge the level of dyspnea in clinical studies, a subjective assessment that dyspnea is worse than at baseline and of at least moderate severity suffices to identify patients who may be at risk for respiratory failure. Physical findings seen with severe exacerbations include tachypnea; accessory muscle use; abdominal paradox; Hoover sign (inspiratory inward motion of the lower, lateral rib cage); cyanosis; and mental status alterations.

In addition to a sputum examination for purulence, a white blood cell count, electrocardiogram, chest radiograph, and arterial blood gas should be obtained to assess the severity of an exacerbation. The widespread use of continuous pulse oximetry and of venous blood gases has decreased, but not eliminated, the need for arterial blood gases. Whereas venous pH values generally agree with arterial values, venous PCO_2 poorly reflects arterial PCO_2 ; nonetheless, a normal venous PCO_2 may be useful in excluding hypercapnia.¹¹⁷ Arterial blood gases provide a rapid assessment of arterial PCO_2 and pH, information that is critical when deciding to place patients in critical care units or to initiate mechanical ventilation and to assess response to therapy. During severe exacerbations, patients with chronic CO_2 retention develop acute-on-chronic hypercapnia, manifested by a drop in pH indicative of retained CO_2 uncompensated by bicarbonate, an important indicator of ventilatory failure that can be detected only by measurement of arterial blood gases.

Medical Therapy

Medical therapy, consisting of bronchodilators, corticosteroids, and antibiotics, should be promptly started in patients with severe exacerbations. Additional therapies, including diuretics, nitrates, or anticoagulation, should be started whenever comorbidities such as congestive heart failure or pulmonary embolism are suspected.

Oxygen should be supplemented routinely to improve hypoxemia, but it should be carefully titrated in patients with CO_2 retention to maintain a target SpO_2 of 88% to 92%. Overzealous oxygen supplementation in such patients has long been known to aggravate CO_2 retention, by either blunting the hypoxic ventilatory drive, increasing physiologic dead space (perhaps due to oxygen-induced bronchodilation in poorly perfused lung regions), or both. Because hypoxemia in COPD patients is usually due mainly to hypoventilation and is easily reversed, initial supplementation with nasal oxygen at 2 L/min is often adequate.¹¹⁸ In patients with severe exacerbations, arterial blood gases should be repeated periodically to assess the effect of oxygen supplementation on arterial PCO_2 .

Figure 99-5 Flow-volume loops for a patient with a normal lung (blue line on right) and one with COPD (brown line on left) along with their respective tidal volume loops (inner black loops with arrows). Note that the expiratory flow during tidal breathing in the COPD patient reaches maximal expiratory flow. During an exacerbation (dashed lines), expiratory flow drops; because the flow during tidal breathing is already maximal, the only mechanism available for maintaining flow is to increase lung volume during tidal breathing (leftward shift of tidal breathing loop, shown by red arrow). Although this strategy maintains expiratory flow, it increases the work of breathing and oxygen consumption, predisposing to inspiratory muscle fatigue and eventual respiratory failure. RV, residual volume. (Redrawn from Hill NS: Current concepts in mechanical ventilation for chronic obstructive pulmonary disease. *Semin Respir Crit Care Med* 20:375–393, 1999.)

Noninvasive Ventilation

Although medical therapy alone is usually effective in mild COPD exacerbation, it is often not sufficient in severe exacerbations. In severe exacerbations, tachypnea, dyspnea, and CO₂ retention may persist or worsen despite initial medical therapy. Before 10 years ago, patients in such a predicament would usually be intubated and mechanically ventilated. If they declined intubation, they were kept comfortable while medical therapy was continued, but they often died. Invasive mechanical ventilation was successful in the majority of cases, but hospital mortality rates were substantial, averaging 30% in several studies.¹¹⁹ Complications of invasive mechanical ventilation were common, including upper airway trauma, pneumothorax, and nosocomial infection, all contributing to patient mortality.¹²⁰

In 1990 Brochard and coworkers¹²¹ demonstrated that the noninvasive delivery of pressurized air into the lungs via a face mask was effective in providing partial ventilatory assistance during COPD exacerbations. These workers used a device designed to provide pressure support that reduced diaphragmatic work of breathing by increasing airway pressure with each inhalation. Later, Appendini and colleagues¹²² demonstrated that combining extrinsic PEEP (to counterbalance the effects of intrinsic PEEP) with pressure support even more effectively reduced the work of breathing in COPD patients than either CPAP or pressure support alone. By reducing the work of breathing, NIV restores the balance between supply and demand for the work of breathing, thereby serving as a “crutch” during COPD exacerbations and halting the progression of respiratory muscle fatigue while medical therapies are given time to work.

Since Brochard’s groundbreaking study, multiple randomized controlled studies and meta-analyses have demonstrated the efficacy of NIV to treat exacerbations of COPD.¹²⁰ When compared with conventional therapy alone, NIV for severe exacerbations of COPD more rapidly improves dyspnea, respiratory and heart rates, arterial PCO₂, and encephalopathy scores.¹²³⁻¹²⁵ In addition, intubation and mortality rates drop precipitously (from roughly 75% and 30% in controls to 25% and 10%, respectively, in NIV-treated patients).^{123,124,126} NIV also lowers complication rates and hospital lengths of stay compared with controls.¹²³⁻¹²⁵ One study has reported that NIV failed to lower intubation or mortality rates or hospital lengths of stay in patients with COPD exacerbations, but it is notable that blood gases were only mildly deranged and there were no intubations or mortality in the control group. This result suggests that patients with relatively mild COPD exacerbations are unlikely to derive benefit from NIV, and the modality should usually be reserved for those with mild to severe symptoms.^{127,128}

Several meta-analyses^{129,130} have concluded that NIV is effective in avoiding intubation (relative risk 0.42 and absolute risk reduction 28%, respectively), reducing mortality (relative risk 0.41 and absolute risk reduction 10%, respectively), and shortening hospital length of stay (by ≈4 days). A recent study on a large cohort of patients (25,628) with COPD exacerbations requiring mechanical ventilation showed reduced mortality, length of stay, and cost with NIV compared to invasive ventilation.^{130a} On the basis of this

evidence, the authors of these meta-analyses, reviews, and guidelines¹²⁹⁻¹³⁵ have advised that NIV should be the ventilatory modality of first choice and should be started early in the course of moderate to severe COPD exacerbations.

Heliox Combined with Noninvasive Ventilation. By virtue of its lower density than nitrogen, helium can be combined with oxygen to lower the airway resistance attributable to turbulent flow. The oxygen concentration can be increased to about 40% in the helium-oxygen mixture but not higher without losing the density advantage of the added helium. Heliox has been combined with NIV to treat patients with COPD exacerbations, with beneficial physiologic responses including reduced airway resistance and more rapid improvements in gas exchange.¹³⁶ However, subsequent randomized, prospective trials on patients with COPD in respiratory failure found that the addition of heliox to NIV offered no significant advantages over NIV alone in terms of intubation or mortality rates or hospital lengths of stay.^{137,138}

COPD Complicated by Pneumonia

COPD patients may develop acute or acute-on-chronic respiratory failure due to an exacerbation complicated by pneumonia. When evaluating a COPD patient with worsening of baseline symptoms, concomitant pneumonia should be considered as a contributing factor. By virtue of impairment in cellular and molecular defense mechanisms and the common use of inhaled corticosteroids, which have been associated with increased pneumonia rates, COPD patients are at risk for pneumonia.¹³⁹ In addition, pneumonia is related to a more severe presentation of community-acquired pneumonia in hospitalized patients, without being a risk factor for mortality.¹⁴⁰

Pneumonia has been associated with a poor outcome in patients treated with NIV.¹⁴¹ However, in one trial on severe community-acquired pneumonia, NIV reduced intubation (21% vs. 50%, $P = 0.03$) and mortality rates, and shortened ICU length of stay (1.8 vs. 6.0 days, $P = 0.04$) compared with standard oxygen therapy. Benefit, however, was confined to the subgroup of patients with underlying COPD.¹⁴² Thus, although the presence of pneumonia is a risk factor for poorer outcome with NIV, COPD patients with pneumonia can still benefit.

Postoperative Patients

Postoperative pulmonary complications are defined as pulmonary abnormalities (such as atelectasis, pulmonary embolism, ALI/ARDS) that arise frequently in the postoperative period, particularly in COPD patients. These complications, due to general anesthesia, postoperative immobility, or to the surgery itself, increase morbidity, mortality, and length of stay.

NIV has been reported to be effective in reducing the need for intubation, ICU length of stay, and mortality rate in post-lung resection patients with acute respiratory insufficiency.^{143,144} Although only a portion of these patients had COPD, accumulating evidence now supports the use of NIV in selected postoperative (including COPD) patients to maintain improved gas exchange and avoid reintubation and its attendant complications. NIV techniques are also

being used prophylactically to reduce secretion problems, atelectasis, and hypoxemia after thoraco-abdominal and major abdominal surgery.¹⁴⁵⁻¹⁴⁷

Postextubation in COPD

Between 10% and 15% of patients develop respiratory failure after a standard extubation, increasing the length of stay on mechanical ventilation and in the ICU and therefore the risk of related complications including mortality.¹⁴⁸⁻¹⁵⁰ In this context, NIV can be used in several ways: (1) to permit earlier removal of the endotracheal tube by assisting ventilation postextubation, (2) to prevent the onset of respiratory failure and need for reintubation in patients at risk for respiratory failure postextubation, and (3) to avoid the need for reintubation in patients who develop frank respiratory failure postextubation.¹⁵¹

Using NIV to allow earlier removal of the endotracheal tube is supported by randomized controlled trials. One trial demonstrated that extubation to NIV after 48 hours of intubation increased overall weaning rate after 60 days (88% vs. 68%), shortened the duration of mechanical ventilation (10.2 vs. 16.6 days), shortened the stay in the ICU (15 vs. 24 days), and improved 60-day survival (92% vs. 72%) (all $P < 0.05$) compared with patients left intubated.¹⁵² A second randomized, controlled trial in patients with “persistent weaning failure” (failure of spontaneous weaning trials on 3 consecutive days) showed that early extubation to NIV significantly reduced ICU and hospital length of stay, incidence of nosocomial pneumonia (from 59% to 24%, $P < 0.05$), complication rate, and hospital and 90-day mortality (odds ratio 3.5).¹⁵³

These randomized studies support use of NIV to facilitate early extubation of invasively ventilated COPD patients. However, if early extubation is contemplated, it should be reserved for carefully selected patients.¹⁵¹ Patients should be recovering from COPD exacerbations, be on 15 cm H₂O or less of pressure support, be able to sustain 5 to 10 minutes of unassisted breathing, have an adequate cough without excessive secretions, be easy to intubate, and have few if any comorbidities.

Using NIV in patients who develop respiratory failure postextubation to avoid reintubation has less support in the literature. Two randomized trials of patients at high risk for extubation failure used NIV prophylactically to prevent reintubation but failed to show the anticipated benefit. In one,¹⁵⁴ NIV provided no reduction in the need for intubation, duration of mechanical ventilation, length of hospital stay, or mortality. In the other, NIV failed to show benefit in these variables and was associated with increased ICU mortality.¹⁵⁵ In the latter study, the increased mortality was thought to be related to a 10-hour longer delay before proceeding with reintubation compared with controls. Furthermore, only 10% of patients in both of these studies had COPD, leading to the speculation that results might have been favorable if more patients with COPD had been enrolled.

This speculation has been borne out by two subsequent randomized, controlled trials, one showing dramatic reductions in respiratory failure, need for reintubation, and mortality in a subgroup of hypercapnic patients,¹⁵⁶ and the other demonstrating that patients with hypercapnia postextubation have a significant reduction in acute ventilatory

failure if treated prophylactically with NIV compared with standard oxygen supplementation.¹⁵⁷ Thus, the best current recommendation is to use NIV selectively in patients with extubation failure, mainly for COPD or other hypercapnic patients, and to avoid delays in intubation should NIV fail.

Do-Not-Intubate Patients

The use of NIV to treat respiratory failure in patients who have declined intubation accounted for 10% of acute applications in one survey.¹⁵⁸ This application has been controversial, with some arguing that there is little to lose because it may reverse the acute deterioration or, at least, provide relief of dyspnea and a few extra hours to finalize affairs.¹⁵⁹ Others have argued that this merely prolongs the dying process, consumes resources inappropriately, and may add to discomfort or counter patients' wishes about avoiding life-prolonging measures.¹⁶⁰ In prospective observational studies of 113¹⁵⁸ and 131¹⁶¹ *do-not-intubate* (DNI) patients treated with NIV, survival to hospital discharge was greater than 50% for COPD and congestive heart failure patients, whereas it was lower (14% to 25%) for those with a diagnosis of hypoxemic respiratory failure (pneumonia) or advanced cancer. Thus, NIV can be used to treat respiratory failure for DNI patients with acutely reversible processes such as COPD exacerbations. Alternatively, it can be used to palliate DNI patients, by alleviating dyspnea or providing temporary support. The patient or family should be informed that NIV is being used as a form of life support that may be uncomfortable and can be removed at any time.

Practical Application of Noninvasive Ventilation

A thorough discussion of the application of NIV is beyond the scope of this chapter, and the reader is referred to Chapter 102 and elsewhere for more complete descriptions.^{132,162} The following sections focus on aspects relevant to applications in COPD patients with acute respiratory failure.

Patient Selection. Selection of appropriate patients is key to the successful application of NIV. The selection process should take into account the patient's clinical characteristics and risk of failure on NIV (Table 99-2). Predictors of success of NIV have been identified^{139,163} (Table 99-3) and include a good neurologic status (and hence more cooperativeness), ability to protect the airway, and only mild-moderate acid-base or gas-exchange derangement. Several studies have also found that improvements in pH, arterial PCO₂, and level of consciousness within the first hour or two of NIV initiation are strong predictors of success.^{139,163} These studies indicate that there is a “window of opportunity” when initiating NIV that opens when patients need ventilatory assistance but closes if they progress too far and become severely acidemic. Ultimately, it becomes a clinical judgment that takes into account the patient's diagnosis that led to the respiratory failure, the need for ventilator assistance, and the absence of contraindications (see Table 99-2).¹⁶⁴

Mask Selection. Tolerance of the mask is key to the success of NIV. Thus, the mask must be a good fit and strapped on sufficiently to control air leaks while avoiding excessive strap tension. For acute applications, the standard

Table 99-2 Selection Criteria for Noninvasive Positive-Pressure Ventilation in Acute Exacerbations of Chronic Obstructive Pulmonary Disease**ESTABLISH NEED FOR VENTILATORY ASSISTANCE**

Moderate to severe respiratory distress
 Tachypnea (RR > 24 breaths/min)
 Accessory muscle use or abdominal paradox
 pH < 7.35, arterial PCO₂ > 45 mm Hg or
 Arterial PO₂/FIO₂ < 200

EXCLUDE PATIENTS WITH CONTRAINDICATIONS TO NONINVASIVE VENTILATION

Respiratory arrest
 Medically unstable (septic or cardiogenic shock, uncontrolled upper gastrointestinal bleeding, acute myocardial infarction with planned intervention, uncontrolled arrhythmias)
 Unable to protect airway
 Excessive secretions
 Uncooperative or agitated
 Unable to fit mask
 Recent upper airway or upper gastrointestinal surgery

FIO₂, fractional concentration of oxygen in inspired gas; NIV, noninvasive ventilation; PCO₂, partial pressure of carbon dioxide; PO₂, partial pressure of oxygen; RR, respiratory rate.

full-face (oronasal) mask is usually preferred because it is better tolerated and avoids the leaking of air through the mouth that can limit the efficacy of nasal masks.¹⁶⁵ Nasal masks, however, may be more comfortable for long-term applications,^{166,167} so transitioning from a full face mask to a nasal mask should be contemplated after the first few days if NIV is to be continued. The helmet, consisting of a plastic cylinder that seals over the neck and shoulders, offers an alternative interface. It is effective for delivery of CPAP in particular. Although difficulty achieving patient-ventilator synchrony has been reported when it is used to deliver pressure support ventilation, increasing the PEEP level to render the mask less compliant seems to help.¹⁶⁶ Within each mask category, many types of masks are available. Practitioners should have a current knowledge of available masks and their proper application in order to maximize the likelihood of NIV success.

Ventilator Selection. In the acute setting, both "critical care" and "bilevel" ventilators (portable pressure-limited devices designed especially for the administration of noninvasive positive pressure ventilation) have been used with similar success rates. A bilevel device designed for use in the acute care setting that includes an oxygen blender and displays waveforms has gained popularity. In addition, many ventilators designed primarily for invasive mechanical ventilation now offer noninvasive modes that are programmed to improve leak compensation, silence "nuisance" alarms that are triggered by air leaks, and permit limitation of inspiratory time to enhance patient-ventilator synchrony.¹⁶⁸ The capabilities of these modes differ considerably, however, and may require additional adjustment if there are mask leaks.¹⁶⁹

NIV Initiation. At the start of NIV, the properly sized mask is placed on the patient's face and attached to the ventilator. Patients often feel more comfortable if they can hold the mask themselves. Pressure-limited modes may be better tolerated than volume-limited modes.¹⁷⁰ Initial ventilator pressures are usually low, to enhance patient comfort and acceptance, but adjusted upward as tolerated to provide adequate ventilatory assistance. Typical initial settings on pressure-limited ventilators are 8 to 12 cm H₂O for inspiratory pressures and 4 to 5 cm H₂O for expiratory pressures (e.g., PEEP), with subsequent adjustments as needed to alleviate respiratory distress or counterbalance intrinsic PEEP or treat hypoxemia. The difference between inspiratory and expiratory pressure is the level of pressure support and should be adequate to alleviate inspiratory effort while avoiding excessive discomfort.

Some ventilators permit adjustments in airflow to enhance synchrony, such as the "rise time," which determines the time to reach the target inspiratory pressure and the adjustable inspiratory time. These may be helpful in optimizing comfort in COPD patients who tend to prefer relatively high inspiratory flows¹⁷¹ (and hence short rise times, often 0.1 sec) and short inspiratory times (usually < 1 sec) to avoid prolongation of delivered inspiratory pressures during expiration.

Oxygenation and Humidification. Most patients with COPD exacerbations do not have severe oxygenation defects

and can be managed successfully with pressure-limited bilevel ventilators. With these ventilators, oxygen is administered at rates up to 15 L/min into ports in the mask or via a T-connector at the proximal end of the ventilator tubing, adjusted to maintain the desired level of oxygenation (usually to an *arterial oxygen saturation* [SaO_2] > 90% to 92%). Because FiO_2 using this arrangement cannot be generated at more than 45% to 50%, ventilators with oxygen blenders are necessary when a higher FiO_2 is needed, such as for patients with COPD complicated by pneumonia. Humidification should be used routinely because it may reduce the work of breathing and enhance comfort and tolerance during NIV.^{166,172,173}

Adaptation and Monitoring. Coaching and encouragement, especially during the first few hours, are critical in achieving adaptation. Judicious administration of low doses of sedatives may enhance patient acceptance. Close bedside monitoring is essential until the patient's respiratory status stabilizes. Although NIV can easily be administered on general medical wards, the acuteness of the patient's illness and need for close monitoring should dictate the site of administration. Acutely ill patients should be treated in an ICU or step-down unit until their condition stabilizes.^{125,174} As shown in Table 99-4, patient comfort and tolerance are key initial goals, together with a reduction in work of breathing and respiratory distress and optimization of patient-ventilator synchrony. Arterial SO_2 is monitored continuously, and blood gases are obtained as is clinically indicated, at baseline and at least once during the first hour or two.

Commonly Encountered Problems and Possible Remedies. Noninvasive ventilation is safe and well tolerated in most properly selected patients. The most commonly encountered problems in COPD patients are similar to those in other patients and are related to the mask, air pressure, or airflow (see Table 99-4). Minimizing air leaks is also an important aim.

Table 99-4 Monitoring Noninvasive Positive-Pressure Ventilation in Chronic Obstructive Pulmonary Disease

ACUTE SETTING

Patient comfort
Mask fit and leak
Patient-ventilator synchrony
Sternocleidomastoid muscle activity
Vital signs (heart and respiratory rate; systemic blood pressure)
Continuous oximetry (until stabilized)
Occasional blood gases (initial and after 30–120 minutes, then as clinically indicated)

CHRONIC SETTING

Patient comfort
Mask fit and leak
Hours of use
Problems with adaptation (e.g., nasal congestion, dryness, gastric insufflation, conjunctival irritation, inability to sleep)
Symptoms (e.g., dyspnea, fatigue, morning headache, hypersomnolence)
Gas exchange (daytime, nocturnal oximetry, blood gases periodically to assess arterial PCO_2)
Polysomnography (if symptoms of sleep disturbance persist or nocturnal desaturation persists without clear explanation)

PCO_2 , partial pressure of carbon dioxide.

Increasing Use of NIV for COPD

The use of NIV in a French ICU increased from 20% of initial ventilator starts to 80% during the 1980s. Concomitantly, the rate of ICU-acquired pneumonia dropped from approximately 20% in 1994 to 8% in 2001.¹⁷⁵ More recent studies using nationwide hospital databases have shown similar trends in the United States, with use of NIV increasing approximately 2.5- to 4.5-fold during the decade from 2000 to 2010, especially in patients older than 85 years,^{175a} accompanied by a drop in the use of invasive mechanical ventilation and a gradual decline in mortality. The mortality rate for patients failing NIV and having to transition to invasive ventilation has crept up over the same time period, raising the concern that NIV may be used occasionally in excessively ill patients who should have been intubated initially.¹⁷⁶

Invasive Mechanical Ventilation

Indications and Patient Selection. Although invasive mechanical ventilation is being used less often for acute exacerbations, it still has an important role in supporting patients who want aggressive support and those who are not eligible or who fail NIV. These and other indications for the use of invasive mechanical ventilation for COPD are listed in Table 99-5.

Invasive mechanical ventilation in COPD must be administered with care to minimize the risk of complications. Excessive tidal volumes and rates must be avoided, and the urge to normalize arterial PCO_2 must be repressed in an effort to minimize intrinsic PEEP and excessive hyperinflation. Excessive respiratory rates reduce the respiratory cycle, shorten expiratory time, and prevent complete exhalation. This problem is aggravated by large tidal volumes. The potential adverse consequence is air trapping and intrinsic PEEP. With intrinsic PEEP, increased intrathoracic pressure reduces venous return and lowers cardiac output. Patients with severe intrinsic PEEP may be hypotensive with

Table 99-5 Indications for Invasive Mechanical Ventilation in Chronic Obstructive Pulmonary Disease

Severe dyspnea with the use of accessory muscles and paradoxical abdominal motion
Respiratory frequency > 35 breaths/min
Life-threatening hypoxemia (arterial PO_2 < 40 mm Hg or arterial PO_2/FiO_2 < 200)
Severe acidosis (pH < 7.25) and hypercapnia (arterial PCO_2 > 60 mm Hg)
Respiratory arrest
Somnolence; impaired mental status
Cardiovascular complications (hypotension; shock; heart failure)
Other complications (metabolic abnormalities; sepsis; pneumonia; pulmonary embolism; barotrauma; massive pleural effusion)
Failure of noninvasive positive-pressure ventilation

FiO_2 , fractional concentration of oxygen in inspired gas; PCO_2 , partial pressure of carbon dioxide; PO_2 , partial pressure of oxygen.

From Pauwels RA, Buist AS, Calverley PM, et al: Global strategy for the diagnosis, management, and prevention of chronic obstructive pulmonary disease: NHLBI/WHO Global Initiative for Chronic Obstructive Lung Disease (GOLD) workshop summary. *Am J Respir Crit Care Med* 163:1256–1276, 2001.

low cardiac output and elevated pulmonary artery wedge pressure due to transmission of the intrathoracic pressure. Their clinical presentation may therefore mimic that of cardiogenic shock. Temporary disconnection from the ventilator can differentiate hemodynamic compromise due to intrinsic PEEP from true cardiogenic shock because the release of intrathoracic pressure permits rapid resolution of the former but not the latter. Intrinsic PEEP may also cause patient-ventilator asynchrony if ventilator triggering is missed when patients cannot reach the triggering threshold due to the inspiratory threshold load.

Recommended Ventilator Settings. Volume-limited or pressure-limited modes can be used, but volume-limited assist-control is the most frequent choice initially and provides control over the tidal volume, which is important in avoiding dynamic hyperinflation. A small tidal volume (e.g., 5 to 7 mL/kg predicted body weight) should be used. Care should be taken to avoid overventilation and alkalemia. The backup respiratory rate for COPD patients receiving invasive mechanical ventilation should be set between 10 and 14/min. Given an inspiratory time of 1 second, if the respiratory rate is 20/min, the expiratory time is only 2 seconds; at a respiratory rate of 15/min, expiratory time increases to 3 seconds. Thus, relatively small changes in rate have large effects on expiratory time. Another way to increase expiratory time is to shorten the inspiratory time by increasing the inspiratory flow rate. However, this strategy is not as fruitful because substantial increases in flow rate result in only minor decreases in inspiratory time. For example, if the inspiratory time is 1 second and inspiratory flow is 60 L/min, an increase in the inspiratory flow rate to 100 L/min decreases the inspiratory time to 0.6 second (if tidal volume is held constant); thus, expiratory time increases only from 2.0 to 2.4 seconds. Furthermore, rapid flow rates may increase the spontaneous respiratory rate¹⁷⁷ and sensation of respiratory distress. COPD patients prefer flow rates in the 60 L/min range and tend to sense faster or slower rates as less comfortable.¹⁷¹

ASTHMA

Acute ventilatory failure due to acute asthma should be unusual if patients adhere to a medical regimen including inhaled corticosteroids, monitor their peak flows, and alter their medical regimen (with the addition of oral steroids) when peak flow declines. Unfortunately, some patients are not treated with optimal regimens: some do not adhere to the regimen, and others have severe exacerbations even with optimal regimens. Although less commonly encountered than in the past, acute ventilatory failure in asthmatics remains a problem. Studies on near-fatal asthma have identified several risk factors for exacerbation, including poor access to health care, substance abuse, nonadherence with therapy, underuse of corticosteroids, and underestimation of the severity of attacks.¹⁷⁸

Medical Management of Acute Asthma

Patients presenting with severe asthma should be promptly treated with systemic, as well as inhaled, corticosteroids and bronchodilators. Rapidly acting β_2 -agonists are administered by inhalation, although no optimal route of admin-

istration or dose has been established. Metered-dose inhalers with spacers or nebulizers may be used, usually every 20 minutes for the first hour. Some centers use continuous nebulization for severe acute asthma. Magnesium, either intravenous or inhaled, has been administered, with some evidence to suggest that it aids aggressive β_2 -agonist therapy, especially in the most severely ill asthmatics.¹⁷⁹

Heliox has been used since the 1930s to lower resistance to flow related to turbulence in the airways of asthma patients, just as in COPD patients. Several randomized, controlled trials of heliox have been performed with patients with acute asthma, but the results are inconclusive. Two demonstrated more rapid improvements in dyspnea and airflow with heliox than with oxygen alone,^{180,181} but another showed no improvement in airflow rates (although dyspnea was reduced more by heliox).¹⁸² The study showing little or no improvement with heliox enrolled less severely obstructed patients than the favorable studies, but a subgroup analysis of sicker patients in the negative study showed no benefit in that subgroup either. A Cochrane analysis concluded that there is no defined role for heliox in treating severe acute asthma.¹⁸³

Ventilatory Management

Assessment of Ventilatory Status. In patients with acute asthma exacerbations, frank ventilatory failure is unusual. Signs of severe respiratory distress, such as excessive use of accessory muscles, extreme tachypnea, or abdominal paradox, warrant the initiation of ventilatory assistance. Arterial blood gases showing normocapnia in a patient with severe respiratory distress should also cause alarm because patients reach a “crossover” point as they fail, when they can no longer sustain hyperventilation but have not become sufficiently fatigued to retain CO_2 . These patients should be monitored closely so that noninvasive ventilatory aids can be initiated promptly in order to avert the need for invasive ventilation with its attendant potential complications.

Continuous Positive Airway Pressure. CPAP alone or NIV may ameliorate respiratory distress in asthmatics by reducing the work of breathing via a direct bronchodilator effect of positive pressure,¹⁸⁴ enhancing the effect of inhaled albuterol and offsetting intrinsic PEEP. However, the unequal distribution of airway resistance in asthma, in contrast to the more simultaneous closure of airways in COPD, creates areas with different expiratory time constants. In this setting, CPAP can promote overdistention of some lung regions. Thus, caution should be exercised when applying CPAP to these patients, at least at levels exceeding 5 cm H_2O , and CPAP should be reduced to 5 cm H_2O if there is no further amelioration of respiratory distress at higher levels.

Noninvasive Ventilation. The role of NIV in the management of asthma exacerbations has not been clearly defined. An early cohort study observed substantial improvements in blood gases (arterial PCO_2 dropping from 65 to 52 mm Hg in the first 2 hours) in 17 patients treated with NIV, only 2 of whom required intubation.¹⁸⁵ More recent studies have shown more rapid improvement in airflow¹⁸⁶ or equivalent improvement with less β -agonist medication.¹⁸⁷ In a

study assessing the effects of bilevel ventilation on airflow in asthmatics, bronchodilators were withheld for the first hour of therapy and the higher bilevel setting was associated with greater improvement in FEV₁ than oxygen therapy alone.¹⁸⁸ These results suggest that positive airway pressure might exert a bronchodilator effect; however, in the absence of evidence of favorable effects on other outcomes like intubation, mortality rate, or ICU or hospital lengths of stay, the benefits of NIV have not been adequately established.

Nonetheless, considering that cohort studies suggest that some patients with severe asthma treated with NIV can avert intubation, a trial of NIV may be considered when patients fail to respond promptly to initial bronchodilator therapy, particularly if they manifest signs of respiratory muscle fatigue, including a respiratory rate of more than 30 breaths/min, accessory muscle use, abdominal paradox, normocapnia in patients with respiratory distress, hypercapnia or hypoxemia. Such patients should be monitored closely in an ICU and intubated if they fail to improve promptly.

Invasive Mechanical Ventilation. Invasive mechanical ventilation in patients with acute ventilatory failure due to asthma should be used as a last resort but is necessary when patients present with coma or delirium or with hemodynamic instability. Another clear indication is failure of medical therapy that may include NIV. Of patients admitted to the ICU with acute severe asthma, about one third have been reported to require invasive mechanical ventilation.^{178,189} Invasive mechanical ventilation is best avoided because of the frequency and severity of the potential complications but, if needed, it should be initiated before a respiratory arrest intervenes. Complications of mechanical ventilation in asthmatics include barotrauma such as pneumothorax and pneumomediastinum, reported in 6.5% of patients in one series,¹⁹⁰ and the need for sedation and paralysis, which should be avoided because of the risk of postparalysis myopathy, ventilator-associated pneumonia, and mortality rates in the 5% to 10% range.¹⁹¹

If invasive mechanical ventilation is necessary, great care must be exercised to minimize the risk of complications, using an approach similar to that used for COPD patients. Excessive respiratory rates and tidal volumes should be avoided, with the ultimate goal of keeping plateau pressures under 30 to 35 cm H₂O. "Permissive hypercapnia,"¹⁹² first described in invasively ventilated asthma patients,¹⁹³ remains a sensible approach in severely obstructed patients. With permissive hypercapnia, plateau pressures are maintained in a relatively safe range (<30 cm H₂O) as the first priority while allowing the CO₂ to rise, in some reports up to 70 to 100 mm Hg. Using this strategy, the major risks of positive-pressure ventilation can be minimized while providing time for the medical therapy to take effect. Bicarbonate or other buffers such as *tris-hydroxymethyl aminomethane* (THAM) can be administered if the pH drops too low, but this is probably not necessary and may not even be effective in raising the pH, a situation also described in patients with acute lung injury.¹⁹⁴ Because of the variability of resistance between airways, some of which may be entirely obstructed, measurement of intrinsic PEEP using the expiratory hold technique may underestimate the severity of regional hyperinflation.¹⁹⁵ When ventilation remains difficult, even

with use of lung-protective ventilation and permissive hypercapnia, the addition of heliox to the ventilator circuit may help (although heliox may alter ventilator performance and not all ventilators can accommodate heliox). As a last resort, extreme measures such as general anesthesia with bronchodilator anesthetics (e.g., halothane)¹⁹⁶ or induced hypothermia may be helpful.

ACUTE VENTILATORY FAILURE DUE TO VASCULAR IMPAIRMENT

An increase in physiologic dead space by disorders affecting the pulmonary vasculature reduces alveolar ventilation in relation to overall minute ventilation. Although hypercapnia might be expected in such a circumstance, it is typically prevented by a modest increase in overall ventilation. Thus, acute ventilatory failure is seldom seen in primary pulmonary vascular disease. In pulmonary thromboembolism, for example, hypercapnia is unusual. Hypercapnia following pulmonary embolism can be seen, however, in patients with a comorbid condition such as severe COPD or a depression of the ventilatory drive by drugs that impair the function of the ventilatory pump. Indeed, acute respiratory acidosis, with or without concomitant worsening in oxygenation, may be the initial manifestation of pulmonary thromboembolism in a patient on controlled mechanical ventilation or with a high cervical spinal cord injury or pharmacologic paralysis who cannot increase minute ventilation.

Another rare circumstance in which acute ventilatory failure may develop as a result of a disorder of the pulmonary circulation is venous air embolism, in which hypercapnia and a marked discrepancy between arterial and end-tidal exhaled CO₂ levels may be observed.¹⁹⁷ Hypercapnia may also complicate the acute chest syndrome in patients with sickle cell disease; one series documented respiratory acidosis in 42% of patients who developed this syndrome.¹⁹⁸

ACKNOWLEDGMENT

The author wishes to thank Dr. Giulia Spoletini for her assistance in revising this chapter.

Key Points

- Ventilatory failure is the consequence of inadequate alveolar ventilation, generally due to poor central drive, neuromuscular disease, profound mechanical derangement of lung parenchyma or chest wall, or some combination of these factors. Depression of central drive is infrequently a major contributor to the development of acute ventilatory failure, except for depression due to drugs.
- Respiratory muscle weakness, regardless of the origin of the impairment (e.g., immunologic, motor neuron disease, myopathic), may either precipitate ICU admission or be acquired in the ICU.
- Clinical assessment including physical examination, measurement of maximal inspiratory and expiratory

pressures, or bedside ultrasound to visualize the diaphragm can be helpful in identifying respiratory muscle weakness.

- COPD exacerbation is the most common cause of acute ventilatory failure seen in acute care hospitals. COPD patients may develop acute or acute-on-chronic ventilatory failure due not only to bronchitis but also to complicating pneumonia, congestive heart failure, pulmonary embolism, or pneumothorax.
- Noninvasive positive-pressure ventilation reduces work of breathing by applying extrinsic *positive end-expiratory pressure* (PEEP) to counterbalance intrinsic PEEP and pressure support to assist inspiration. It is especially useful in exacerbations of COPD but may also play a role in other forms of acute ventilatory failure due to COPD, such as in facilitating extubation of those who fail a trial of spontaneous breathing or in avoiding reintubation in those who fail extubation.
- Invasive mechanical ventilation can generally be accomplished using small tidal volumes of roughly 6 mL/kg, which limits intrinsic PEEP in COPD, reduces the risk of ventilator-induced lung injury in those with parenchymal lung disease, and minimizes the circulatory compromise that can complicate restrictive chest wall conditions.
- When initiating noninvasive ventilation, there is a “window of opportunity” that opens when patients need ventilatory assistance but closes if they progress too far and become severely acidemic. Improvements in pH, arterial PCO₂, and level of consciousness within the first hour or two of noninvasive ventilation are strong predictors of success.

- In patients with respiratory failure due to asthma or COPD, attempts to normalize arterial PCO₂ generally lead to dynamic hyperinflation, thereby risking hypotension and pneumothorax; instead, “permissive hypercapnia” is used to limit minute ventilation and maintain airway pressures in a safe range while allowing the arterial PCO₂ to rise.

HYPOXEMIC RESPIRATORY FAILURE

Hypoxemic respiratory failure has classically been defined as an arterial PO_2 of less than 60 mm Hg. It is distinguished from hypercapnic respiratory failure ($PCO_2 > 45$ mm Hg), although the two conditions often coexist. There are a number of important qualifications to this definition that must be made. The threshold of 60 mm Hg is somewhat arbitrary and reflects the shape of the oxyhemoglobin dissociation curve, marking the arterial PO_2 below which the saturation of hemoglobin with oxygen falls precipitously in most people. An important caveat is that it is important whether hypoxemic respiratory failure is acute (over hours to days) or chronic (over weeks to months) as it has implications not just for diagnosis and treatment, but also for the physiologic adaptations to hypoxemia that develop over time. For example, an individual living at high altitude may have an arterial PO_2 less than 50 mm Hg because of a low inspired partial pressure of oxygen. Such an individual could well be asymptomatic because of acclimatization to that environment and would not be considered to have hypoxemic respiratory failure even if she had an arterial PO_2 of 45 mm Hg. It is also important to realize that this definition of hypoxemic respiratory failure (arterial $PO_2 < 60$ mm Hg) encompasses a broad spectrum of severity of illness. For example, both a patient on a general medical ward with community-acquired pneumonia and a mechanically ventilated patient on 100% oxygen in the critical care unit can fulfill the definition.

This definition of hypoxemic respiratory failure (based on the arterial PO_2) does not fully address the importance of oxygenation at the level of the tissues. Oxygen delivery to the tissues is the product of cardiac output and oxygen content. Oxygen content is critically dependent on the hemoglobin concentration and its saturation with oxygen; although the oxygen saturation depends on arterial PO_2 (as described by the oxyhemoglobin dissociation curve), the direct contribution of dissolved oxygen to blood oxygen content is very low under most conditions. In other words, in the anemic patient or in patients with very low cardiac output, tissue hypoxia may exist despite a seemingly adequate arterial PO_2 . Finally, as indicated earlier, both hypoxemic and hypercarbic respiratory failure may

coexist. A patient may initially present with isolated hypoxemia yet, upon tiring, may develop hypercarbia. Analogously, hypoventilation can cause both hypercarbia and hypoxemia.

This chapter focuses on acute hypoxemic respiratory failure. In particular, much of our discussion pertains to the etiology and management of hypoxemia at the “severe” end of the spectrum. This is not to say that mild hypoxemia is not important; certainly the condition of a patient on the medical ward with pneumonia and mild hypoxemia can deteriorate and the patient would require intubation and mechanical ventilation.

CLASSIFICATION OF HYPOXEMIA

The traditional approach to the causes of arterial hypoxemia classifies them into five pathophysiologic mechanisms: decreased inspired PO_2 , hypoventilation, impaired diffusion, *ventilation-perfusion* (\dot{V}/\dot{Q}) mismatch, and right-to-left shunt. Whereas hypoxemia from \dot{V}/\dot{Q} mismatch is responsive to supplemental oxygen, hypoxemia from a right-to-left shunt is not. This physiologic approach is probably most useful in understanding how a particular disease causes hypoxemia, but is not usually very illuminating when trying to make a specific diagnosis, other than in situations in which a patient is hypoxemic due to profound hypercapnia. In a hospital setting, a decreased inspired PO_2 can usually be excluded, because most patients will be placed on supplemental oxygen. Hypoventilation can rapidly be excluded if the patient is not hypercapnic. Impaired diffusion by itself is not an important cause of acute hypoxemia, in that oxygen transfer across the alveolar-capillary membrane to red blood cells is usually perfusion-limited, not diffusion-limited. What this means is that there is usually ample time for diffusion of oxygen, even in the presence of intrinsic lung disease. In sum, most patients in the intensive care unit with acute hypoxemic respiratory failure have some combination of \dot{V}/\dot{Q} mismatch and right-to-left shunt.

Another classification of acute hypoxemic respiratory failure is structural-anatomic (Fig. 100-1). Causes of acute arterial hypoxemia can be classified based on whether the primary pathology is located in the air spaces, interstitium, heart and pulmonary vasculature, airways, or pleural

Figure 100-1 Schematic depicting a structural-anatomic approach to the diagnosis of acute hypoxemic respiratory failure.

space. Such an approach would quickly lead one to consider such causes as pulmonary edema or pneumonia, hypersensitivity pneumonitis, pulmonary embolism, bronchospasm, and pneumothorax. Although disorders involving other structures such as the central nervous system and respiratory muscles can lead to hypoxemia, these causes would be expected to have associated hypercarbia.

CLINICAL FEATURES AND DIAGNOSTIC APPROACH

The clinical features of acute hypoxemic respiratory failure vary based on the underlying cause. Assuming an intact drive to breathe and that the patient has not fatigued, the hypoxemic patient is usually tachypneic and tachycardic. Cyanosis of the lips or tongue (so-called central cyanosis) would indicate that the concentration of reduced (deoxygenated) hemoglobin is greater than 5 g/100 mL.

Given the extensive differential diagnosis of acute hypoxemic respiratory failure and the often urgent need for therapy, the clinician must be practical yet thoughtful. A basic history should be obtained to identify risk factors for cardiac dysfunction, pulmonary infection or aspiration, venous thromboembolism, or obstructive lung diseases. In the setting of trauma to the chest, pneumothorax, hemothorax, and pulmonary contusion must be considered. Further questions to identify less common causes of acute hypoxemic respiratory failure can be posed as appropriate. A focused physical examination of the cardiac and respiratory systems often can establish the presence or absence of congestive heart failure or a focal area of consolidation or effusion. Similarly, the diagnosis of a pneumothorax is more satisfying (and prompt) when made on physical examination rather than later, after chest imaging.

Implementation of therapy is simultaneous with the diagnostic workup. As always, this starts with the "ABCs" of airway, breathing, and circulation. Once the ABCs are assured, the patient should be given supplemental oxygen (if coexistent hypercapnia is present, care must be taken in

the dose of supplemental oxygen) and intravenous access should be obtained. Continuous cardiac monitoring and pulse oximetry should be available.

The initial investigations are dictated by the findings on history and physical examination. However, all patients should have a chest radiograph, an electrocardiogram, and routine blood work, including a complete blood count with differential and serum chemistry. An arterial blood gas should be obtained and the alveolar-arterial PO_2 gradient should be calculated; a normal alveolar-arterial PO_2 gradient in the setting of arterial hypoxemia suggests hypoventilation as the sole cause of the hypoxemia. The blood gas is also useful for diagnosing other acid-base disturbances and hemoglobinopathies such as carbon monoxide poisoning. The need for further investigations, including bronchoscopy, computed tomographic angiography of the chest, and echocardiography, depends on the results of the initial assessment. A completely normal chest radiograph in the setting of hypoxemic respiratory failure narrows the differential diagnosis substantially. In this uncommon circumstance, the clinician should consider pulmonary embolism and right-to-left shunts (i.e., intracardiac or pulmonary arteriovenous malformations) as possibilities. A more common scenario is that the chest radiograph of a patient with pneumonia can appear surprisingly normal (or may show only a "small" opacity) due to concomitant intravascular volume depletion. Once intravascular volume has been restored, the extent of the opacity can be appreciated.^{1,2}

CAUSES OF ACUTE RESPIRATORY FAILURE

In a large multicenter international prospective cohort study of patients requiring mechanical ventilation, the most common reported causes of acute respiratory failure were postoperative respiratory failure, pneumonia, congestive heart failure, sepsis, and trauma.³ In a small prospective cohort study that included 41 patients with hypoxemic

respiratory failure, chronic obstructive pulmonary disease and pneumonia were the most common causes.⁴ Other data from small randomized controlled trials of noninvasive ventilation identified congestive heart failure, pneumonia, trauma, acute respiratory distress syndrome, and mucous plugging as the most common causes of respiratory failure.^{5,6} However, in these studies, patients with certain diseases were excluded, including those with chronic obstructive pulmonary disease^{5,6} and asthma,⁶ limiting the ability to generalize from these findings. Indeed, in the one randomized study that specifically enrolled patients with acute hypoxemic respiratory failure, only patients with bilateral lung opacities on chest radiography were included.⁶

For a detailed discussion of many of the specific causes of acute hypoxemic respiratory failure (e.g., pneumonia), refer to the appropriate chapters in this book. The remainder of this chapter focuses on a particular subtype of acute hypoxemic respiratory failure, known as *acute respiratory distress syndrome* (ARDS).

ACUTE RESPIRATORY DISTRESS SYNDROME

DIAGNOSIS AND EPIDEMIOLOGY

Diagnosis

ARDS is characterized by noncardiogenic pulmonary edema, lung inflammation, hypoxemia, and decreased lung compliance. Unlike some disorders (e.g., coronary artery disease), ARDS, as its name suggests, is a syndrome, reflecting a constellation of clinical and physiologic observations thought to represent a common pathology. In coronary artery disease, narrowing of the coronary vasculature and disruption of an unstable atherosclerotic plaque are known to underpin the symptoms of angina and unstable angina, respectively. A diagnostic “gold standard,” namely coronary angiography, exists. In contrast, the pathogenesis of ARDS remains elusive and there is no gold standard diagnostic test. The heterogeneity of the clinical conditions associated with ARDS (discussed later) would be consistent with the possibility that ARDS is in fact a collection of different diseases that have not yet been separately identified. These problems necessarily permeate any discussion or research into ARDS, and this chapter is no exception.

The first description of ARDS appeared in a remarkable case series reported in 1967.⁷ Ashbaugh and colleagues described 12 patients ranging in age from 11 to 48 years who presented with respiratory distress, hypoxemic respiratory failure, and patchy bilateral opacities on chest radiographs (Fig. 100-2). Most of the cases were preceded by severe trauma or viral infection and the onset of symptoms was relatively rapid, with most patients developing respiratory distress within 48 to 72 hours of the beginning of their illness. Many patients required positive pressure ventilation and exhibited low respiratory system compliance, and some experienced improvement in oxygenation with the application of *positive end-expiratory pressure* (PEEP). This syndrome was initially termed the *adult* respiratory distress syndrome to distinguish it from the respiratory distress syndrome seen

Figure 100-2 Acute Respiratory Distress Syndrome. Frontal chest radiograph in a patient with acute respiratory distress syndrome. Note the presence of bilateral opacities.

in infants. Subsequently, recognizing that the syndrome can also develop in children, it was renamed the *acute* respiratory distress syndrome.

The cases described by Ashbaugh and colleagues generated interest and research into ARDS. Unfortunately, the lack of specific diagnostic criteria and an understanding of the pathogenesis of the disorder made it difficult to undertake research and to compare studies. In 1988, a formalized and expanded definition of ARDS was proposed that consisted of three parts: (1) determining whether the illness was acute or chronic, (2) determining whether there were any associated risk factors or medical conditions (e.g., sepsis),⁸ and (3) assigning points based on the severity of pulmonary dysfunction (the Lung Injury Score), as measured by the degree of hypoxemia, the level of PEEP required, the respiratory system compliance, and the degree of radiographic abnormality. An average score was calculated and a final value greater than 2.5 was used to diagnose ARDS. One advantage of this system was its description of associated medical conditions, which might be pertinent to the etiology of ARDS. Because ARDS from different etiologies might reflect different pathogenesis and perhaps confer a different response to therapy, it was thought that knowing the cause of ARDS might be important in the conduct and comparison of studies. The definition, however, made no attempt to exclude cardiogenic pulmonary edema; it was assumed that clinicians would do so automatically.

In 1994, a consensus conference of American and European investigators published their definition of ARDS, which was widely adopted.⁹ Aiming for simplicity, ARDS was defined as a syndrome of acute onset, with bilateral opacities on chest radiography consistent with pulmonary edema, pulmonary artery occlusion pressure of 18 mm Hg or less (or absence of clinical evidence of left atrial hypertension), and hypoxemia as measured by the ratio of the *arterial partial pressure of oxygen* (arterial PO_2) to the *fraction of oxygen inspired* (FI_{O_2}). Recognizing that there was a spectrum of severity of the disease, the consensus panel recommended that arterial PO_2/FI_{O_2} ratio ≤ 300 would define

an entity termed *acute lung injury* (ALI). ARDS was the most severe form of ALI and was diagnosed when arterial $\text{PO}_2/\text{FIO}_2 \leq 200$. The simplicity of the definition led to its general acceptance by clinicians and its incorporation into clinical research. At the same time, such a straightforward definition could not take into account the heterogeneity of the disease or the ambiguity of clinical practice.

For example, the requirement for bilateral opacities on chest radiograph is open to interpretation. One study presented a random series of chest radiographs from intubated hypoxemic patients (arterial $\text{PO}_2/\text{FIO}_2 < 300$) to an international group of expert clinicians, the majority of whom conduct clinical research on ARDS. The clinicians were asked to examine each radiograph and to decide whether it fulfilled the *American-European Consensus Conference* (AECC) definition of ARDS (bilateral opacities consistent with pulmonary edema). This select group of physicians demonstrated only moderate agreement (kappa statistic 0.55) in their classification of the radiographs; when the percentage of radiographs deemed to be consistent with ARDS by each physician was examined, the percentages were evenly distributed from a low of 36% to a high of 71%.¹⁰ Another larger study on the issue also demonstrated only moderate agreement when two physicians were asked to rate radiographs on the presence or absence of diffuse bilateral opacities consistent with ARDS. However, with prior training and discussion, the agreement between an intensivist and a radiologist in the rating of the films was excellent.¹¹

The AECC definition has also been criticized for not taking the level of PEEP into consideration. Clinicians have long appreciated that applying PEEP can improve oxygenation, an observation that was noted in the first description of ARDS. This implies that the arterial PO_2/FIO_2 will change with changes in the level of PEEP; indeed, a patient who meets the AECC criteria for ARDS may no longer meet them once PEEP has been increased.¹² It has also been shown that patients meeting the AECC definition for ARDS can be stratified based on their response to standard ventilator settings 24 hours later; many of the patients at that point have a lesser degree of hypoxemia and a significantly lower mortality rate.¹³ Thus, the AECC definition, while simple to use, encompasses a heterogeneous group of patients.

In 2012, the so-called Berlin definition of ARDS was developed to address some of these limitations (Table 100-1).^{14,15} The degree of hypoxemia was stratified into mild, moderate, and severe based on the arterial PO_2/FIO_2 ratio and a requirement for a PEEP level of 5 cm H_2O or greater was included (whether applied by endotracheal tube or, in the setting of mild disease, by noninvasive ventilation). The term ALI was eliminated (but is used as needed in this chapter to help readers interpret older literature). Given that the use of pulmonary artery catheters has fallen off dramatically due to a demonstrated lack of benefit,^{16,17} the need for a pulmonary arterial wedge pressure measurement was eliminated and instead it was recommended that objective testing (e.g., echocardiography) be performed to exclude cardiogenic edema if no risk factor for ARDS could be identified. "Acute" was explicitly defined as ARDS developing within 1 week of a known risk factor. Although considerable effort went into its design, when compared with the AECC criteria, the Berlin definition is only slightly better at predicting mortality attributable to ARDS.¹⁴

Table 100-1 Berlin Definition of ARDS

Criterion	Definition
Timing	Within 1 week of a known precipitant, or new/worsening respiratory symptoms
Chest imaging (chest radiograph or CT scan)	Bilateral opacities—not fully explained by effusions, lobar/lung collapse, or nodules
Origin of edema	Respiratory failure not fully explained by cardiac failure or fluid overload If no risk factor for ARDS is present, need objective assessment (e.g., echocardiogram) to exclude hydrostatic edema
Oxygenation	
Mild	200 mm Hg < arterial $\text{PO}_2/\text{FIO}_2 \leq 300$ mm Hg with PEEP or CPAP ≥ 5 cm H_2O
Moderate	100 mm Hg < arterial $\text{PO}_2/\text{FIO}_2 \leq 200$ mm Hg with PEEP ≥ 5 cm H_2O
Severe	Arterial $\text{PO}_2/\text{FIO}_2 \leq 100$ mm Hg with PEEP ≥ 5 cm H_2O

CPAP, continuous positive airway pressure; FIO_2 , fraction of inspired oxygen; PEEP, positive end-expiratory pressure.

Adapted from Ranieri VM, Rubenfeld GD, Thompson BT, et al: Acute respiratory distress syndrome: the Berlin Definition. *J Am Med Assoc* 307(23):2526–2533, 2012.

Two additional points should be made about the diagnosis of ARDS. First, while physicians properly think of ARDS as being distinct from cardiogenic pulmonary edema, it is important to acknowledge that many patients with ARDS will have left atrial hypertension during the course of their illness.¹⁸ Second, despite the increasing use of B-type natriuretic peptides as diagnostic tools for acute congestive heart failure, their ability to distinguish ARDS from cardiogenic pulmonary edema is unclear.^{19,20}

Incidence

Given the multitude of definitions and the difficulty in making a diagnosis of ARDS, it is not surprising that determining the incidence of the disease has been challenging. The reported incidence of ARDS has ranged from 75 per 100,000 population²¹ to as low as 1.5 per 100,000²² in Europe; the European numbers appear fairly constant over time.²³ Many older studies did not use the AECC definition and did not include ALI; the Berlin definition is too recent to have been widely studied. The incidence of ALI has been estimated to be 78.9 cases per 100,000 person-years.²⁴ One study calculated an incidence of ALI of 22 cases per 100,000 using data from a large prospective trial of ARDS and from the American Hospital Association.²⁵ One of the methodologic strengths of the study was its inclusion of cases of ALI over a 3-year period, thereby decreasing the impact of seasonal variability. The heterogeneity in the literature of the estimates of incidence may reflect differences in the methodology of the various studies, but may also reflect true variation. Regional differences in genetic or environmental factors and specific disease-associations such as cardiopulmonary bypass or lung transplant may account for some of the regional variability in the incidence of ALI.²⁶

Risk Factors

Sepsis, aspiration of gastric contents, and multiple transfusions (>15 units/24 hours in one study) are associated with the highest risk for development of ARDS.²⁷ In particular, ARDS develops in almost 40% of patients with sepsis. The presence of more than one presumed risk factor for ARDS may increase the incidence of ARDS, although the sample sizes of these subsets have been quite small.²⁷ ARDS has been seen to develop in more than one third of patients receiving massive blood transfusion and in one fourth of patients with multiple trauma (one or more pulmonary contusions, multiple fractures, multiple transfusions).²⁸

One of the predisposing factors for the development of ARDS is a history of chronic alcoholism (relative risk, 2.0; 95% confidence interval, 1.3–2.9).²⁹ This relationship has been shown to remain significant after adjustment for gender, at-risk diagnosis, and severity of illness. Among those in whom ARDS developed, patients with a history of alcoholism had a higher mortality rate than those without such history (odds ratio, 6.3; 95% confidence interval, 2.2–20.4).²⁹ The mechanisms of this association are unknown.

The same researchers examined whether patients with diabetes might be protected against development of ARDS, the rationale being that hyperglycemia is known to impair neutrophil function, and neutrophils are thought to be central to the pathogenesis of ARDS (see [Pathogenesis](#)). More than 100 patients admitted to the intensive care unit with septic shock were followed prospectively for the development of ARDS. Over a 2-year period, diabetes was associated with a significantly decreased risk of ARDS (relative risk, 0.53; 95% confidence interval, 0.28–0.98), which persisted after adjustment for the source of sepsis and other potential confounders. Interestingly, there was no difference in mortality between patients with ARDS who did and did not have diabetes.³⁰

A systematic overview of studies examining potential risk factors for ARDS concluded that the strongest evidence of a causal relationship was for sepsis, trauma, multiple transfusions, aspiration of gastric contents, pulmonary contusion, pneumonia, and smoke inhalation.³¹ More recently, active or passive exposure to cigarette smoke has been associated with the development of ARDS after trauma.³²

The heterogeneity of risk factors for ARDS is remarkable. At the AECC, investigators divided the known risk factors into those thought to cause *direct* lung injury (e.g., pneumonia) and those in which the mechanism of lung injury was thought to be *indirect* (e.g., pancreatitis) ([Table 100-2](#)). While conceptually attractive, this classification scheme may not reflect underlying differences in the mechanisms, severity, or outcome of lung injury.³³ This issue is discussed in more detail in the section on outcomes.

ETIOLOGY AND PATHOGENESIS

Overview of Pathophysiology

In the past, ARDS was also called noncardiogenic pulmonary edema, a descriptive term that nonetheless reflected

Table 100-2 Conditions Associated with ARDS, Categorized by Possible Mechanisms of Injury

Direct injury	Indirect injury
Pneumonia	Sepsis
Aspiration	Major trauma
Pulmonary contusion	Multiple blood transfusions
Toxic inhalation	Pancreatitis
Near-drowning	Cardiopulmonary bypass
Reperfusion injury (e.g., after lung transplantation)	Drug overdose
	Adverse effect of medication

what was known of the pathogenesis of the disorder. Unlike congestive heart failure, in which elevated left-sided cardiac pressures cause hydrostatic pulmonary edema, in ARDS, the edema fluid that fills the alveoli is exudative in origin. In other words, the alveolar-capillary barrier exhibits increased permeability, allowing for the leakage of protein-rich fluid into the air spaces. Alveolar filling leads to decreased respiratory system compliance as well as right-to-left shunting and profound hypoxemia. Although arterial PCO₂ is generally within the normal range, dead space ventilation is significantly increased, as demonstrated by elevated minute ventilation. Pulmonary hypertension is also commonly observed in ARDS, and a number of mechanisms have been proposed including hypoxic vasoconstriction, intravascular fibrin deposition in the pulmonary capillaries, and compression of blood vessels by the positive pressure ventilation used to treat the disorder. This section reviews the pathology of ARDS and discusses current theories regarding its pathogenesis. Much of the research into ARDS has focused on determining the basis for the increase in alveolar-capillary permeability.

Pathology

The pathologic features of ARDS have classically been described using three overlapping and sequential stages.³⁴ In the first or exudative phase of lung injury, the pathologic findings have been termed *diffuse alveolar damage*. There are hyaline membranes lining the alveolar walls and protein-rich edema fluid in the alveolar spaces, as well as epithelial disruption and infiltration of the interstitium and air spaces with neutrophils. Areas of hemorrhage and macrophages can also be found in the alveoli. This phase, which is thought to last for approximately 5 to 7 days, is followed in some patients by the so-called proliferative phase. At this point, hyaline membranes are reorganized and fibrosis begins to be observed. Obliteration of pulmonary capillaries and deposition of interstitial and alveolar collagen may be observed, along with a decrease in the number of neutrophils and the extent of pulmonary edema. This proliferative stage has traditionally been described as being followed by a fibrotic phase, essentially emphasizing the appearance of pulmonary fibrosis in a subset of patients with persistent (i.e., >2 weeks) ARDS. More recently, it has been realized that areas of fibrosis may actually develop sooner than usually appreciated: elevated levels of N-terminal procollagen peptide III, thought to represent collagen synthesis, can be detected in bronchoalveolar lavage fluid of patients with ARDS as early as 24 hours into the course of the illness. In addition, the bronchoalveolar lavage fluid from

these patients has been shown to stimulate cultured fibroblasts to proliferate.³⁵ These and other observations have led some investigators to hypothesize that fibroproliferation may be initiated simultaneously with (rather than after) inflammatory lung injury.³⁶

Alveolar-Capillary Membrane

If ARDS is a disorder of increased alveolar-capillary permeability, it stands to reason that the pulmonary microvascular endothelium or the alveolar epithelium (or both) must be involved in its pathophysiology. Damage to the alveolar epithelium is thought to be a key event.³⁷ Once ARDS has begun, the importance of the alveolar epithelium is also clear: Type II pneumocytes must differentiate into type I cells to help cover the denuded epithelial surface, while both type I and II cells express the Na^+, K^+ -ATPase, which is thought to be important in clearance of edema fluid (discussed later). Injury to type II pneumocytes impairs the production and metabolism of surfactant. In addition to damage to the alveolar epithelium, loss of lung endothelial barrier integrity is both necessary and sufficient for the development of ARDS.^{38,39} How the alveolar-capillary membrane is damaged is not known for certain, although mediators of epithelial and endothelial apoptosis⁴⁰ and neutrophils are suspected of playing a role (see later).

Surfactant. Surfactant is a complex mixture of phospholipids and surfactant proteins that reduces alveolar surface tension. Many researchers have described alterations to the surfactant obtained from patients with ARDS. There are decreased amounts of surfactant-related protein and decreased dipalmitoylphosphatidylcholine and phosphatidylglycerol in the surfactant of patients with ARDS. The proportion of large (active) to small (inactive) aggregates of surfactant is diminished, due to both decreased production of surfactant and increased conversion of the large to small forms. In addition, plasma proteins that have leaked through the alveolar-capillary barrier may interfere with surfactant function.⁴¹ For example, damage to surfactant protein A has been demonstrated in patients with ARDS.⁴² The impairment in surfactant function observed in ARDS would theoretically predispose alveolar units to collapse. In addition, surfactant proteins have been found to have antimicrobial properties,^{43,44} although whether the loss of these properties is relevant to the pathogenesis of ARDS is not known. Indeed, despite the litany of abnormalities in surfactant that have been described,⁴⁵ the extent to which these alterations contribute to the pathogenesis of ARDS remains controversial: unlike the *neonatal* respiratory distress syndrome, in which a deficiency of surfactant underlies the pathophysiology of the disease, it is possible that the abnormalities of surfactant in ARDS are the result rather than the cause of altered physiology. Indeed, four large randomized controlled trials of exogenous surfactant supplementation in ARDS failed to demonstrate any improvement in mortality or requirement for mechanical ventilation⁴¹ (see Treatment). Only one trial, using calfactant (a natural surfactant, distinct from the synthetic surfactants used in previous trials) in pediatric patients with ARDS, has shown any benefit⁴⁶; whether this is due to the unique surfactant used in this study or to differences

between the patients enrolled in this trial and the negative trials is unknown.

Neutrophils and Other Inflammatory Mediators

Histologically, one of the hallmarks of ARDS is the accumulation of neutrophils in the microvasculature of the lung.⁴⁷ As key players in innate immunity, neutrophils can generate an impressive array of cytotoxic compounds. These include reactive oxygen species, cationic peptides (e.g., defensins), eicosanoids, and proteolytic enzymes such as leukocyte elastase. In addition, once activated, neutrophils release growth factors and cytokines (e.g., *tumor necrosis factor* [TNF]- α and *interleukin* [IL]-1 β) that may enhance the inflammatory response. Given this destructive potential, it has long been theorized that neutrophils may be central to the pathogenesis of ARDS⁴⁸ (Fig. 100-3). There is an abundance of clinical and preclinical data to support this hypothesis. For example, in humans with ARDS following sepsis, bronchoalveolar lavage neutrophilia is associated with a poor prognosis.⁴⁹ Neutrophil-depleted mice exposed to hyperoxia develop less lung injury than normal mice.⁵⁰ Similarly, in a hamster model of ARDS induced by endotoxin inhalation, the administration of a specific inhibitor

Figure 100-3 Role of neutrophils in the pathogenesis of acute lung injury. Activated neutrophils exit the bloodstream and transmigrate across the alveolar-capillary membrane, releasing cytokines, proteases, reactive oxygen species, and other compounds. Although crucial to host defense against pathogens, the compounds secreted or released by the neutrophil have the capacity to damage the tissue of the host. (Adapted from Lee WL, Downey GP: Leukocyte elastase: physiological functions and role in acute lung injury. A state of the art review. *Am J Respir Crit Care Med* 164:896–904, 2001.)

of neutrophil elastase (even hours after administration of endotoxin) prevented the development of lung injury.⁵¹

If neutrophils are involved in the pathogenesis of ARDS, some defect in their regulation must be invoked. For example, in an uncomplicated bacterial pneumonia, the pulmonary inflammatory response is limited by counter-regulatory processes that prevent tissue damage. Whether this regulation is ineffective or insufficient in ARDS is a fascinating and unanswered question.⁵²

One of the earliest manifestations of ARDS, even before hypoxemia, is a transient leukopenia due to sequestration of neutrophils in the lung microvasculature.⁵³ The average pulmonary capillary is smaller than the average neutrophil, and neutrophils therefore have to deform to pass through the microvasculature. Activated neutrophils “stiffen” and cannot negotiate narrow capillary segments.⁵⁴ Inhibitors of actin polymerization can abrogate this stiffening, implicating a change in the actin cytoskeleton in neutrophil sequestration in the lung.⁵⁵ Neutrophil sequestration also involves interactions between molecules on the surface of the neutrophil and the lung capillary endothelium. For example, in rabbits, blocking the adhesion molecule L-selectin on the surface of the neutrophil prevented neutrophil sequestration in alveolar capillaries induced by exposure to endotoxin.⁵⁶

After the initial sequestration, neutrophils must translocate (via diapedesis) across the alveolar-capillary barrier to the alveolar space. The determinants of this seemingly simple movement remain incompletely understood. Integrins on the surface of the neutrophil are thought to mediate emigration of neutrophils from the pulmonary circulation in response to some, but not all, inflammatory stimuli.⁵⁷ Proteases secreted by the alveolar epithelium, in concert with regional cytokine production and glycosaminoglycans on the epithelial surface, may act together to form a chemotactic gradient for neutrophils to follow.⁵⁸

Many studies are focusing on the mechanisms of neutrophil activation whereas others are focusing on the interaction between platelets and neutrophils and how mutual activation may contribute to ARDS or sepsis.⁵⁹⁻⁶² Other studies have looked at various components of intracellular signal transduction pathways, such as kinases (enzymes that phosphorylate substrates) and transcription factors. For example, one such kinase is the p38 mitogen-activated protein kinase, which is activated when cells are stimulated with *lipopolysaccharide* (LPS).⁶³ Activation of this kinase stimulates TNF- α production and macrophage inflammatory protein-2 release (a chemotactic factor for macrophages).⁶⁴ Interestingly, inhibition of p38 mitogen-activated protein kinase in mice, even hours after the mice are exposed to aerosolized LPS, attenuates neutrophil chemotaxis and migration from the lung microvasculature into alveoli.⁶⁵ Another kinase often discussed in the context of inflammation is phosphatidylinositol 3-kinase. This enzyme phosphorylates phosphatidylinositol, a lipid-derived second messenger whose phosphorylated forms have been implicated in a myriad of intracellular signaling events. Phosphatidylinositol 3-kinase γ is preferentially activated in neutrophils exposed to IL-8 or fMLP (a bacterial-derived peptide).⁶⁶ Despite exposure to intraperitoneal endotoxin, phosphatidylinositol 3-kinase γ knockout mice displayed decreased neutrophil accumulation, cytokine production,

and lung injury compared to control mice. The neutrophils in the lung of the knockout mice also demonstrated diminished activation of NF- κ B, an important transcription factor known to mediate the up-regulation of numerous cytokines and proinflammatory mediators.⁶⁷

There are many potential mechanisms by which activated neutrophils might mediate ALI. In addition to secreting cytokines and growth factors that might stimulate the local and systemic inflammatory response, neutrophils release defensins⁶⁸ and generate reactive oxygen species that can mediate tissue damage.⁶⁹ In animal studies, inhibition of the assembly of NADPH oxidase (the major source of reactive oxygen species) by apocynin has been shown to attenuate sepsis-induced lung injury.⁷⁰ The *nitric oxide synthase* (NOS) pathway has also been implicated in mediating lung injury; knockout mice lacking the gene for inducible NOS developed less severe lung injury than wild-type animals upon injection with LPS.⁷¹

In addition, neutrophils contain proteolytic enzymes that may be involved in the pathogenesis of ALI. In particular, both neutrophil elastase and metalloproteinases have been extensively studied.⁵² Because of its ability to degrade multiple substrates including growth factors and cytokines, neutrophil elastase may be involved in regulation of the inflammatory response. It has also been shown to degrade epithelial and endothelial cadherins, proteins that are major components of adherens junctions, which hold cells together. It is possible that elastase-mediated destruction of cadherin could predispose to alveolar flooding. Despite its potential to cause unwanted tissue damage, *neutrophil elastase* (NE) is likely crucial to host defense. In NE-deficient mice, the administration of intraperitoneal *Klebsiella pneumoniae* causes 100% mortality within 48 hours, whereas mortality in normal mice was only 50%.⁷² However, NE-deficient mice are paradoxically resistant to normally lethal doses of LPS. Furthermore, mice that lack both NE and another neutrophil protease (cathepsin G) are protected against alveolar damage induced by endotoxic shock.⁷³ These apparently contradictory results suggest that NE, while important in a regulated inflammatory response, may nonetheless participate in inflammatory injury under certain circumstances. In numerous studies of multiple different experimental models in multiple species of animals, NE has been shown to play an important role in the pathogenesis of ALI. Whether it is as important in the development of ARDS in *humans* remains unanswered. A clinical trial of a leukocyte elastase inhibitor in ARDS was halted because preliminary analysis suggested lack of efficacy.⁷⁴

Metalloproteinases may also be important mediators of leukocyte-mediated lung injury. Elevated concentrations of the matrix metalloproteinases gelatinase A and B have been found in the epithelial lining fluid of patients with ARDS.⁷⁵ Mice lacking the genes for gelatinase B or stromelysin 1 had less severe injury in an animal model of ALI.⁷⁶ As mentioned earlier, matrilysin (matrix metalloproteinase 7) has been shown to regulate the formation of a chemotactic gradient and the transmigration of neutrophils across the alveolar epithelium in a mouse model of ALI.⁵⁸ Finally, administration of an inhibitor of elastase and metalloproteinases (chemically modified tetracycline-3) attenuated ALI after cardiopulmonary bypass in pigs.⁷⁷

Despite the emphasis on neutrophils as potentially causative for lung injury, it is important to note that ARDS has certainly been described in patients with profound neutropenia.^{78,79} Indeed, it is possible that the neutrophil infiltration observed in some cases of ARDS is adaptive (i.e., a physiologic response to a primary injury) rather than destructive. At present, however, it is generally believed that neutrophils are a causative factor in the development of most cases of ARDS. Comparatively little is known about the mechanisms of neutrophil-independent ARDS and this must be a goal of future investigations.

Inflammation and Coagulation

Because one of the most common precipitants for ARDS is sepsis, it is hoped that therapies for sepsis may either prevent or improve the outcome of ARDS. Our current concept of sepsis is that there is an initial inflammatory state, with up-regulation of inflammatory cytokines such as TNF- α and IL1 β and recruitment and activation of inflammatory cells such as neutrophils. This early stage of inflammation is followed by a relatively depressed immunity, in which the patient is vulnerable to nosocomial infections.⁸⁰ The theory that dysregulation of the inflammatory response is responsible for sepsis has led to the search for agents that would selectively block components of the inflammatory pathway. It has also been appreciated that there are important connections between the molecular cascades that regulate both inflammation and coagulation; for example, TNF- α causes an increase in thrombin and fibrin formation, while fibrin fragments themselves are known to be chemotactic for neutrophils.⁸¹ TNF- α increases tissue factor expression on endothelium and inhibits fibrinolysis, both of which favor fibrin formation. *Activated protein C* (APC), an endogenous anticoagulant, has direct and indirect anti-inflammatory effects, which include reducing levels of IL-6 and attenuating neutrophil activation in sepsis.^{82,83} Because sepsis is the most common cause of ARDS and because abnormalities of coagulation are very common in sepsis, investigators have wondered whether altered coagulation is involved in the genesis of ARDS. How this might happen is largely speculative, but intraalveolar, interstitial, and intravascular fibrin deposition have all been observed in patients with ARDS. Indeed, fibrin is a major component of hyaline membranes. Intraalveolar fibrin has been postulated to serve as a nidus for fibroblast proliferation and potentially, as ALI resolves, as a stimulus for pulmonary fibrosis. Fibrin might contribute as well to ongoing lung injury through its chemotactic properties, and intravascular fibrin deposition, as in microthrombi, might contribute to the elevated pulmonary vascular pressures observed in ARDS.

Interest in the role of coagulation in the pathogenesis of ARDS was buttressed in part by observations in animal studies that anticoagulation can attenuate the severity of sepsis-induced lung injury,⁸⁴ although studies in humans have been disappointing. Indeed, a small randomized controlled trial of APC in patients with ALI was stopped prematurely due to lack of efficacy,⁸⁵ and APC was pulled from the market after a large multicenter trial showed it provided no mortality benefit in patients with septic shock.⁸⁶

Other molecular determinants of inflammation continue to be elucidated. Some data have implicated transforming growth factor- β in an animal model of ALI.⁸⁷ In one study,

transforming growth factor- β was postulated to cause increased alveolar epithelial cell permeability by depleting intracellular glutathione levels.⁸⁸ Other investigators have attempted to improve the endogenous counter-inflammatory response; in one study, the gene for heat shock protein 70 was ligated to an adenoviral promoter, and the resultant recombinant construct was administered into the lungs of rats in which ARDS had been induced by cecal ligation and perforation. Administration of the heat shock protein 70 construct increased heat shock protein 70 expression specifically in the lung; remarkably, this increased expression was associated with a significant reduction in pulmonary edema and inflammation and even mortality.⁸⁹ Indeed, mice deficient in heat shock protein 70 showed increased mortality and lung injury after cecal ligation and perforation.⁹⁰ The mechanisms underlying this effect are not clear, but may involve suppression of the proinflammatory transcription factor NF- κ B or decreased lung parenchymal apoptosis.⁹¹

Na⁺ and Water. Na⁺ channels at the apical surface of alveolar epithelial cells mediate intracellular Na⁺ uptake from the alveoli. This creates an osmotic gradient that causes alveolar fluid to follow, thereby allowing for the clearance of pulmonary edema. Na⁺,K⁺-ATPases in the basolateral membrane of the epithelial cell exchange intracellular Na⁺ for extracellular K⁺, maintaining the intracellular sodium concentration low enough for the apical Na⁺ resorption to continue. This process allows for the net removal of Na⁺ and fluid from the alveolar space, and can be accelerated (at least experimentally) by catecholamines.

Dysfunction of either the apical Na⁺ channels or the basolateral Na⁺,K⁺-ATPases (or both) have been postulated to be involved in the pathogenesis of ARDS. For example, it is known that hypoxia decreases epithelial Na⁺ reabsorption by impairing the expression of subunits of the epithelial Na⁺ channel.⁹² Hypoxia also decreases the activity of both the apical Na⁺ channel⁹³ and the Na⁺,K⁺-ATPase.⁹⁴ In an animal model of hemorrhagic shock-induced lung injury, the normal up-regulation of alveolar fluid reabsorption in response to catecholamines was absent. This defect was attributed to an increase in *nitric oxide* (NO) in the lung, possibly due to an effect on β -adrenergic receptor signaling.⁹⁵ In a study of patients with ARDS, alveolar fluid clearance was calculated from the change in alveolar fluid protein concentrations. When patients were stratified by their rate of fluid clearance, those with the highest rates had the shortest duration of mechanical ventilation and the lowest mortality.⁹⁶ In a model of *ventilator-induced lung injury* (VILI) in rats, overexpression of the Na⁺,K⁺-ATPase improved the clearance of lung liquid.⁹⁷ However, attempts to increase alveolar fluid clearance in a clinical setting (e.g., by β -adrenergic agonists) have so far been disappointing⁹⁸; further details are provided later under Novel Therapies (see also Chapter 9).

Angiopoietins. Angiopoietins are peptides involved in embryonic vascular development. Of the four angiopoietins that have been identified, *angiopoietin 1* and *angiopoietin 2* (ANGPT1 and ANGPT2, respectively) are the best described. ANGPT1 is expressed by numerous cell types while ANGPT2 is mostly limited to endothelial cells. Both act on the TIE2

receptor tyrosine kinase that is found predominantly on endothelial cells and hematopoietic stem cells.⁹⁹ A number of observations have generated interest in the potential role of these proteins in the pathophysiology of ARDS. First, elevated levels of ANGPT2 have been described in patients with sepsis and ARDS¹⁰⁰ and its administration to mice causes pulmonary vascular leak.^{101,102} The effect of ANGPT2 in disrupting endothelial cell integrity could be reversed in vitro by ANGPT1. Second, overexpression of ANGPT1 was protective against both endotoxin-induced septic shock and ALI in mice¹⁰³; a similar benefit was observed using a synthetic peptide agonist of the TIE2 receptor.³⁸ While the cellular mechanism of these effects remains uncertain and is the subject of intense investigation,^{104,105} the data to date emphasize the important role for endothelial cells in the development of and recovery from ARDS.

Ventilator-Induced Lung Injury

Although mechanical ventilation for ARDS may be lifesaving, there is abundant preclinical and clinical evidence that it can also be harmful.^{106,106a} While it was quickly recognized that excessive airway pressure could lead to *barotrauma* (Fig. 100-4), including pneumothorax, pneumomediastinum and subcutaneous emphysema, attention has since turned to subtler but more common manifestations of lung injury related to mechanical ventilation. Mechanical ventilation can induce pulmonary edema by causing increases in both epithelial and endothelial perme-

Figure 100-4 Barotrauma as a consequence of acute respiratory distress syndrome. Note the presence of a pneumothorax, pneumomediastinum, pneumoperitoneum, and subcutaneous air in this patient receiving positive-pressure ventilation. (Courtesy Thomas E. Stewart, MD, University of Toronto.)

ability.¹⁰⁶ Indeed 40 years ago Webb and Tierney demonstrated that ventilation of rats with high peak airway pressures could lead to severe pulmonary edema,¹⁰⁷ and more than 20 years ago, investigators noted that mechanical ventilation could produce a form of increased permeability pulmonary edema remarkably similar to ARDS.¹⁰⁸ Now, the accumulated evidence suggests that certain mechanical ventilation strategies may aggravate if not induce ARDS in some patients.¹⁰⁹

A major mechanism causing VILI is overdistention of lung units, rather than the absolute airway pressure per se. Normal rats ventilated with high airway pressure due to a high tidal volume developed increased permeability, whereas rats ventilated with smaller tidal volumes, but with the same end-inspiratory pressure (obtained by strapping the chest walls of the rats) did not develop increased permeability.¹⁰⁶ Rats were also ventilated with low airway pressure using negative inspiratory pressure (applied at the chest wall) and high tidal volumes. Their results demonstrated that the rats ventilated with high tidal volumes had significantly more edema than others. In particular, the negative (low) pressure and high tidal volume group had the worst edema. These important observations, confirmed in other species,¹¹⁰ led to the appreciation that large tidal volumes, rather than high airway pressures per se, are an important determinant of ventilator-induced pulmonary edema. The term *volutrauma* was created to recognize this fact.

The repetitive opening and closing of terminal lung units associated with mechanical ventilation is also considered to be detrimental. The mechanism of this injury, which has been termed *atelectrauma*,¹¹¹ is thought to be the high shear stresses generated at the interface of collapsed and aerated tissue when a collapsed airway is reopened.¹¹² Theoretically, PEEP should be helpful in minimizing this injury by keeping the lung recruited and promoting greater lung homogeneity; any such advantage of PEEP would have to be balanced against the potential harm caused by a potentially greater overdistention of lung units due to the higher PEEP levels (see Video 100-1).

It is important to point out that patients with ARDS may be especially vulnerable to VILI because of the heterogeneous nature of the pulmonary parenchymal injury. On computed tomography scans of the lungs, normal-appearing lung and densely consolidated injured lung are both seen; as a consequence, there are marked regional differences in lung compliance¹¹³ (Fig. 100-5). A tidal volume designed to inflate an entire lung would preferentially inflate the normal-appearing areas, potentially leading to overdistention and volutrauma. Patients with ARDS may similarly be more vulnerable to atelectrauma. Although some evidence suggests that normal lungs can tolerate at least short periods of cyclic opening and closing of airways from mechanical ventilation,¹¹⁴ injured lungs, such as in ARDS, would be exposed to much higher shear stresses and would not be expected to fare as well.¹¹⁵

Over the past 15 years, there has been a growing appreciation that VILI is not only a mechanical injury, but also reflects an underlying complex cellular and molecular response. The term *biotrauma* has been coined to emphasize this change in thinking.¹¹⁶ In our understanding of VILI, one of the most significant advances made is that mechanical ventilation per se can induce both a local and systemic

Figure 100-5 Axial chest CT in a patient with acute respiratory distress syndrome. Note the presence of dense consolidation with air bronchograms in the dependent dorsal lung with relative sparing of the ventral lung. (Courtesy Thomas E. Stewart, MD, University of Toronto.)

inflammatory response. In animal studies of ex vivo lungs, it has been shown that, compared to a control ventilation strategy with moderate tidal volumes and PEEP, ventilation either with high tidal volumes or with zero PEEP causes elevations in lung lavage levels of inflammatory cytokines. Lungs ventilated both with high tidal volumes and with zero PEEP had a synergistic elevation in cytokine levels.¹¹⁷ This inflammatory response to an injurious ventilation strategy has also been shown to extend beyond the lung. In an acid aspiration rat model of lung injury, a ventilatory strategy using high tidal volumes and zero PEEP was associated with an increase in blood levels of various cytokines; this was not observed in groups ventilated with a small tidal volume or in the group ventilated with the large tidal volume but higher PEEP levels.¹¹⁸

Most importantly, similar observations have been made in humans with ARDS. In one study, patients were randomized to “lung-protective” ventilation, in which the tidal volume was set to avoid overdistention and PEEP was set above the lower inflection point of the pressure volume curve.¹¹⁹ The control group received a strategy that would have been considered conventional ventilation at the time. While alveolar-lavage and plasma cytokine levels declined in the lung-protective group, they rose significantly in the control group. Post hoc analyses revealed a significantly higher number of ventilator-free days in the lung-protective group than in controls and significant correlations between the development of multisystem organ failure and plasma cytokines. The impact of ventilator strategy on the development of biotrauma can be remarkably quick. Within 1 hour after switching patients from a protective ventilatory strategy, Stuber and colleagues found an increase in a number of proinflammatory cytokines in the lungs and plasma of patients with ARDS.¹²⁰

Mortality and Complications

As discussed in the section on outcomes, patients with ARDS often die of the systemic inflammatory response syndrome and multiorgan dysfunction. Hence, the observation that mechanical ventilation can influence pulmonary and systemic cytokine levels is intriguing. Taken together, these findings suggest that mechanical ventilation has the poten-

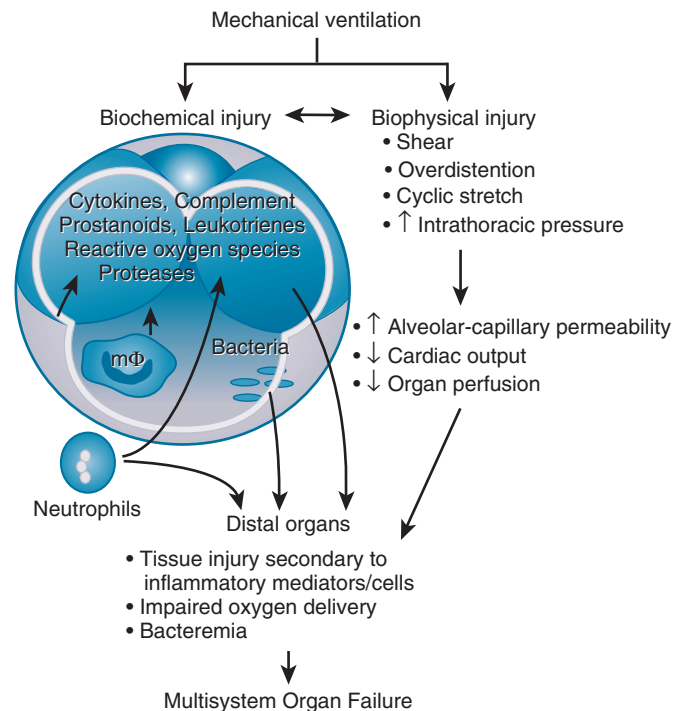

Figure 100-6 Potential mechanisms by which mechanical ventilation might cause or contribute to multisystem organ failure. Alveoli are represented showing the multiple mechanisms by which the mechanical ventilation may induce inflammatory damage and mechanical damage which can then “spill over” to affect distal organs. mφ, macrophage. (Redrawn from Slutsky AS, Tremblay LN: Multiple system organ failure: is mechanical ventilation a contributing factor? *Am J Respir Crit Care Med* 157:1721–1725, 1998.)

tial not only to injure the lungs, but also to lead to a loss of compartmentalization of the pulmonary inflammatory response. Systemic dissemination of this response could be associated with the development of systemic inflammatory response syndrome and potentially with multisystem organ failure (Fig. 100-6).¹²¹ In one study, injurious mechanical ventilation in rats not only caused elevated plasma and lung cytokine levels, but also caused increased renal epithelial cell apoptosis and associated renal dysfunction.¹²² Furthermore, pretreatment with either IL-10 (an anti-inflammatory cytokine) or IL-22 (a member of the IL-10 family that has immunoregulatory and tissue protective properties) reduced lung injury and reduced mortality in animal models of VILI.¹²³

Finally, patients with ARDS often require very high inspired fractions of oxygen. The toxic effects of hyperoxia on the lung have been well described,¹²⁴ and the histologic appearance mirrors that of human ARDS. Oxygen toxicity is thought to be mediated by the formation of both reactive oxygen and nitrogen species, which can damage tissues by a multitude of mechanisms,⁶⁹ and hyperoxia appears to worsen VILI.¹²⁵ Antioxidants have been considered as a potential therapeutic strategy for preventing and treating ARDS, although clinical trials have so far been disappointing (see [Therapy](#)).

Genetic Determinants

To date, relatively little is known about which genes might affect the development or prognosis of ARDS. Genome-wide

association studies have suggested a number of candidate genes,¹²⁶⁻¹²⁹ including those coding for angiopoietin 2 and the angiotensin-converting enzyme,¹³⁰ that might affect the incidence and/or outcome of ARDS. Subsequent studies have reported conflicting results.^{131,132} The heterogeneity of patients with ARDS is likely to make it difficult to identify clinically important genetic associations except in clearly defined subsets of patients.

MORTALITY AND COMPLICATIONS

Mortality

The mortality rate for ARDS has decreased over the past 10 to 15 years, with a number of studies describing a decline in the rate from more than 60% to less than 40% since 1993.¹³³⁻¹³⁵ Mortality rates in adults and children with ARDS appear to be similar.¹³⁶ The reasons for the improvement in survival over time are not known, although some have attributed it to better supportive care in the intensive care unit and the use of lung-protective strategies.

Predictors of Poor Prognosis

Despite the prominence of hypoxemia among the clinical manifestations of ARDS, early trials did not find that the severity of hypoxemia early in the course of the illness was a good predictor of subsequent mortality.¹³⁷ Pulmonary injury scoring systems, such as the Lung Injury Score and the ARDS score, have been shown to predict a prolonged (>2 weeks) requirement for intubation and ventilation,¹³⁸ while scoring systems that measure the overall severity of illness, such as the Simplified Acute Physiology Score, correlate better with survival.¹³⁹ The classic teaching is that patients with ARDS do not usually die of refractory hypoxemia, which may seem paradoxical given that hypoxemia is frequently the focus of resuscitative efforts. In fact, most patients with fatal ARDS die of sepsis and multiorgan failure.^{140,141} The explanation for this apparent paradox is unknown, although it has been hypothesized that injurious mechanical ventilation during the course of ARDS may be involved.¹²¹ As discussed earlier, ventilation using excessive tidal volumes has been shown to cause elevations in pulmonary and systemic cytokine levels, and has been linked in an animal model to apoptosis of renal cells and renal dysfunction.¹²²

The mortality rate from ARDS varies depending on the precipitant. The highest risk of death has consistently been reported in sepsis, while ARDS in the setting of major trauma has a much better prognosis.¹⁴² In addition, it is known that chronic liver disease,¹³⁷ older age,¹⁴³ chronic alcoholism,²⁹ and nonpulmonary organ dysfunction¹³⁷ are associated with higher mortality from ARDS. Other predictors of death from ARDS have included a history of organ transplantation and infection with human immunodeficiency virus,¹⁴⁴ while one study described a higher mortality rate in men and also in African-Americans compared to non-African-Americans.¹⁴⁵

As mentioned earlier, risk factors for ARDS have been classified as being pulmonary or nonpulmonary in origin, thereby leading to an injury to the lung by *direct* or *indirect* means. It remains unclear whether this distinction has prognostic importance. In one prospective cohort study of

ARDS patients, investigators found a trend toward higher mortality in patients with a pulmonary precipitant, although the difference was not statistically significant.¹⁴⁶ In contrast, the ARDS Network investigators retrospectively analyzed the data from their large randomized study of low tidal volume ventilation versus traditional tidal volume ventilation. While confirming that the mortality rate for ARDS was highest in patients with sepsis and lowest in patients with trauma, there was no difference in mortality, days off the mechanical ventilator, or the development of organ failure between patients with pulmonary or nonpulmonary risk factors. In addition, there was no statistically significant evidence that the low tidal volume strategy was less efficacious in any subgroup.¹⁴² A meta-analysis came to a similar conclusion.³³ The consensus group that developed the Berlin definition of ARDS decided not to include pulmonary versus nonpulmonary ARDS as distinct categories.

Because hypoxemia is not a reliable predictor of mortality from ARDS, investigators have searched for other lung-specific markers of prognosis. In one prospective study of 179 patients with ARDS, a multiple logistic regression was performed to identify which clinical and physiologic variables predicted mortality.¹⁴⁷ The analysis found that the dead space fraction (as calculated by the Bohr equation) was elevated in ARDS and was an independent predictor of mortality. For every increase of 0.05 in the dead space fraction, the odds of death from ARDS increased by 45%. The mechanism of this association is not known: it is possible that the pulmonary vascular injury in ARDS that accounts for the increase in dead space may be important to overall outcome.

The development of pulmonary fibrosis is also thought to connote a worse prognosis. Elevated procollagen III levels, thought to be indicative of collagen synthesis, have been found in the pulmonary edema fluid of patients with ARDS and have been shown to correlate with increased mortality.^{148,149} In another study, 22 of 25 consecutive patients with ARDS underwent transbronchial biopsies of the most abnormally appearing areas on the chest radiographs. In those whose biopsies showed any fibrosis, the mortality rate was significantly higher than in patients whose biopsies showed no fibrosis.¹⁵⁰ Of note, there is evidence in animal models that the stress induced by mechanical ventilation may lead to lung fibrosis via epithelial-mesenchymal transition.¹⁵¹

Finally, there is extensive interest in the identification of biomarkers to predict outcome from ARDS. For instance, associations have been reported between elevated levels of cytokines such as IL-6 and IL-8¹⁵² and growth factors such as angiopoietin 2¹⁰⁰ and a poor prognosis from ARDS. However, even a combination of biomarkers when used together with clinical predictors is only slightly more predictive for mortality than the clinical predictors alone.¹⁵³

Complications

ARDS is complicated by ventilator-associated pneumonia in about 30% to 65% of cases (see also Chapter 34). In this setting, ventilator-associated pneumonia usually develops more than 5 to 7 days after the onset of mechanical ventilation and is often preceded by colonization of the lower respiratory tract by potential pathogens.¹⁵⁴ The likely organisms

include nonfermenting gram-negative rods, methicillin-resistant *Staphylococcus aureus*, and *Enterobacteriaceae*.¹⁵⁵ Although the development of VAP prolongs the duration of mechanical ventilation in ARDS, it does not appear to increase mortality.^{154,156,157} Making a definitive diagnosis of VAP in patients with ARDS can be challenging, because patients with ARDS already have radiographic abnormalities, and not uncommonly have leukocytosis and fever. If diagnostic techniques such as bronchoalveolar lavage or protected specimen brushes are used, the yield is higher when the lung is sampled bilaterally and when the patient is off antibiotics.^{157,158}

Another feared complication of ARDS is barotrauma (pneumothorax, pneumomediastinum, subcutaneous emphysema, eFig. 100-1) due to the effect of positive pressure ventilation in heterogeneous lungs with diminished compliance. Because most patients with ARDS will be supine (rather than erect), diagnosing a pneumothorax requires vigilance; the radiographic appearance of a pneumothorax is different and can be subtler in the supine patient (e.g., air in the costophrenic angle, the “deep sulcus” sign). Data from a number of prospective studies suggest that the incidence of barotrauma in ARDS currently is about 10% or less.^{109,159,160}

THERAPY

Supportive Care

One of the first goals of therapy in ARDS is to treat the underlying cause. In particular, patients with sepsis may respond to aggressive source control, including antibiotics and, when appropriate, surgical débridement and drainage. In patients with ARDS and sepsis of unknown origin, both the lung and the abdomen should be considered and excluded as foci of infection.^{140,141} Additional goals are the prevention of complications and the provision of supportive care (e.g., nutrition, ventilation) to allow the body time to heal. Typically, such treatment should include prophylaxis against gastrointestinal stress ulceration and deep venous thrombosis.

Hemodynamic Management

The optimal approach to hemodynamic management in ARDS has become less controversial with the publication of studies comparing different strategies. Before these studies, it had been unclear whether clinicians should attempt to diurese to decrease pulmonary edema at the expense of potentially causing hypovolemia and shock or to liberalize fluids to maintain perfusion.

This issue was addressed by a large multicenter randomized controlled trial from the ARDS Network, made up of investigators at multiple American hospitals. The trial randomized 1000 patients with ARDS to one of two highly protocolized fluid strategies: through the administration of fluids, diuretics, or vasoactive agents, the two protocols targeted either a higher or lower intravascular pressure (as measured by a pulmonary artery or central venous catheter) for 7 days. Patients randomized to the conservative fluid strategy (targeting a lower intravascular pressure) had significant improvements in oxygenation and more ventilator-free and intensive care unit-free days than the patients in

the liberal strategy. Importantly, patients in the conservative arm did not have a higher incidence of dialysis or shock than those in the liberal arm; in addition, mortality rates in the two arms were similar. Thus, the results of this study suggest that conservative administration of fluids is safe and beneficial to patients with ARDS.

At first, this recommendation may seem at odds with the principle of early goal-directed therapy, whereby patients with sepsis are aggressively resuscitated with fluid in accordance with the randomized controlled trial reported by Rivers and coworkers.¹⁶¹ However, the apparently disparate results of these clinical trials are not difficult to reconcile. First, it is important to note that patients in the ARDSNet study were enrolled an average of 24 hours after meeting the criteria for ALI, much later than the 6-hour window in the study by Rivers. In addition, the study protocol of the ARDSNet trial was strictly designed to avoid aggravating or inciting shock or pulmonary edema.

One last caveat is that the ARDSNet study used a very complex algorithm for fluid administration that may not be widely adopted. A simplified protocol has since been proposed but has not been validated.¹⁶² In the meantime, we recommend that clinicians manage fluids conservatively in patients who are not in shock, nonetheless taking care to avoid overdiuresis and hypovolemia.

Clinicians had historically inserted a pulmonary artery catheter into patients with pulmonary edema to help establish the diagnosis and to guide therapy. The consensus from numerous clinical trials is that, for most patients, the information from a pulmonary artery catheter does not improve outcome.¹⁶ For this reason, we do not recommend the routine use of these catheters in patients with ARDS.

Which fluid to use in patients with ARDS remains an open question. The use of starch-based colloids has fallen out of favor in patients with severe sepsis, because of a randomized trial that found a higher incidence of renal failure in patients with severe sepsis receiving 10% pentastarch compared to patients receiving Ringer lactate.¹⁶³ Whether pentastarch has the same detrimental effect in patients with ARDS without severe sepsis is unknown. On a theoretical basis, the use of albumin is appealing, because it would increase intravascular oncotic pressure and predispose to less pulmonary edema. A small placebo-controlled study in ARDS demonstrated that a regimen of albumin and furosemide infusions over 5 days caused a substantial and statistically significant improvement in oxygenation accompanied by a decrease in heart rate. However, most of the patients had ARDS as a result of trauma, with less than 5% having sepsis. There were no differences in important clinical outcomes (e.g., mortality), although the study was not powered to address these issues.¹⁶⁴ A follow-up study established that the beneficial effect on oxygenation was due to the albumin, not the furosemide.¹⁶⁵ Although a large clinical trial of patients admitted to the intensive care unit has concluded that albumin was as safe as crystalloid,¹⁶⁶ the study did not specifically enroll patients with ARDS and only looked at short-term outcomes. It is also important to remember that as a blood product, the administration of albumin is associated with a very small but finite risk of transmissible diseases. Thus, pending further trials, the role of albumin in the management of patients with ARDS is unclear.

Nutrition

It has been hypothesized that manipulations in diet could enhance the immune system and improve the outcome of inflammatory diseases such as sepsis and ARDS. Such strategies have involved supplementing enteral feeds with one or more of arginine, glutamine, omega-3 fatty acids, and antioxidants.

One small randomized study examined the effect of a modified enteral feed containing eicosapentaenoic acid, gamma-linolenic acid, and various antioxidants compared to a control enteral feed in patients with ARDS.¹⁶⁷ The authors found that the modified feed improved oxygenation, reduced the number of neutrophils in alveolar lavage fluid, decreased length of stay, and decreased the requirement for mechanical ventilation. In a more recent study, modified enteral feeds (containing eicosapentaenoic acid, gamma-linolenic acid, and various antioxidants) also improved oxygenation, although clinically important outcomes were unchanged.¹⁶⁸ Many other studies of modified enteral feeds (often called immunonutrition) have been conducted in less well-defined populations of critically ill patients, with conflicting results. A meta-analysis on the topic highlighted the heterogeneity of the studies and suggested that the effect of immunonutrition varied depending on the group of patients being studied.¹⁶⁹ At this point, the role of immunonutrition in the management of ARDS remains unclear.

A related issue in this area has been how much enteral nutrition should be given. In a recent randomized controlled trial, the rate of enteral feeding (e.g., at a regular rate versus a low, so-called trophic rate that delivered one third as many calories) did not affect the outcome of ALI.¹⁷⁰

Pharmacotherapy

Attempts to develop pharmacologic therapies for ARDS have been frustrating and largely unsuccessful, with no pharmacotherapies that unequivocally reduce mortality from ARDS, despite a multitude of randomized controlled trials of dozens of potential agents.¹⁷¹ Despite the heterogeneity of the agents that have been evaluated, three generalizations can be made:

1. Despite showing effectiveness *in vitro* or in animal studies, most potential therapies have failed to reduce mortality or other important clinical outcomes in human clinical trials.
2. A number of agents improve oxygenation but do not affect mortality from ARDS.
3. Post hoc analyses of subsets of patients from a number of studies of various agents suggest benefit, but prospective data are lacking.

The following section reviews the biologic rationale for various potential therapies for ARDS, with an emphasis on evidence from clinical trials when available.

Corticosteroids. Because of the presumed inflammatory pathophysiology underlying ARDS, a number of trials of high-dose corticosteroids have been performed. In some, the goal was the prevention of ARDS in patients at risk (e.g., with septic shock), while in others, steroids were given in established ARDS. The usual regimen was methylprednisolone 30 mg/kg every 6 hours for 1 to 2 days. None of the trials using this treatment regimen showed any benefit from

the use of steroids,^{172,173} and one showed a higher incidence of infection in patients who received steroids.¹⁷⁴ More recently, the use of steroids has been contemplated later in the course of ARDS, during the fibroproliferative phase. Persistently elevated plasma cytokine levels have been shown to correlate with worsened survival from ARDS, prompting some to theorize that late ARDS (>7 days after onset) is characterized by persistent inflammation that might be responsive to treatment with steroids. A small study randomized 24 patients with late ARDS to 2 mg/kg of methylprednisolone (followed by a 32-day taper) or placebo. Patients in the steroid group had lower mortality, improved oxygenation, decreased organ dysfunction, and earlier extubation, but also had a higher (but not statistically significant) rate of infection.¹⁷⁵ However, these data are difficult to interpret because of the small sample size and the number of patients who crossed over to the alternate therapy.

A randomized placebo-controlled trial of 180 patients with ARDS of at least 7 days' duration was subsequently performed by the ARDS Network.¹⁷⁶ Patients were randomized to either placebo or a single dose of 2 mg/kg of methylprednisolone followed by 0.5 mg/kg every 6 hours for 14 days, then every 12 hours for 7 days, then tapering. Although the patients randomized to steroids showed improvements in the number of ventilator-free and shock-free days (during the first 28 days) as well as in oxygenation, there was no difference in 60-day mortality. A subgroup analysis revealed that patients who received steroids more than 14 days after the onset of ARDS had a significantly increased 60- and 180-day mortality rate. The issue of whether to use steroids in late ARDS remains controversial,¹⁷⁷ but it seems reasonable to consider steroids in patients who are not improving between about days 7 and 14 in that benefit has been suggested in subgroups and harm has not been proven.

Vasodilators. Prostaglandin E₁ is a vasodilator that has been studied as a potential therapy for ARDS, based largely on its putative anti-inflammatory properties. In vitro and preclinical studies in animals suggested that prostaglandin E₁ given parenterally, especially when administered in a liposome, had the potential to decrease neutrophil activation. Despite promising early data,¹⁷⁸ a large randomized double-blind multicenter trial of liposomal prostaglandin E₁ found no improvement in survival or in ventilator dependence even though the drug improved oxygenation.¹⁷⁹

Prostacyclin is another vasodilator which, when administered by nebulizer, acts selectively on the pulmonary vasculature. Because the aerosolized solution tends to go to the better ventilated areas of the lung, vasodilatation of the branches of the pulmonary artery that supply these areas lead to improved \dot{V}/\dot{Q} matching and improved oxygenation. Although prostacyclin has been used as rescue therapy for refractory hypoxemia and is well tolerated,¹⁸⁰ there are no large randomized studies and no placebo-controlled studies of its use in ARDS.^{181,182}

NO is a highly reactive gas formed endogenously by NOS from the amino acid arginine. It stimulates cellular guanylate cyclase, leading to increased cyclic guanosine monophosphate levels. It acts as a potent vasodilator, and when given by inhalation, NO causes vasodilatation of the pulmonary circulation. NO is rapidly inactivated in the

bloodstream by combining with hemoglobin to form methemoglobin, which is usually rapidly metabolized and does not accumulate to levels that are thought to be toxic (i.e., methemoglobin < 5%). Because of this rapid inactivation, NO is a selective vasodilator that does not affect the systemic circulation. Like aerosolized prostacyclin, NO causes the most vasodilatation in the areas of the lung that are best ventilated, thereby improving \dot{V}/\dot{Q} matching.¹⁸³ In addition, NO has both antiinflammatory and proinflammatory properties, although the contribution of these properties to its effects in a clinical setting is unclear.¹⁸⁴ NO can also react with oxygen and water to form toxic metabolites, such as NO₂ and nitrous and nitric acid, although at concentrations of NO of less than 40 ppm, this problem is not usually clinically significant. A soda lime absorber can be placed in the inspiratory limb of the NO circuit in order to remove any NO₂ before the inspired gas reaches the patient.

In the largest randomized, double-blind, placebo-controlled study of NO in ARDS to date, more than 170 patients were randomized to different doses of NO (from 1.25 to 80 ppm) or placebo. Although approximately 60% of patients had a significant improvement in oxygenation within 4 hours of NO administration, there was no difference in survival or in liberation from mechanical ventilation between patients receiving NO and those in the placebo group.¹⁸⁵ In addition, the initial improvement in oxygenation from NO was not sustained over the course of study. There were few adverse effects of NO, and for patients who were administered less than 40 ppm, methemoglobin and NO₂ levels were the same as in the placebo group. The results of this study confirmed the findings of other smaller unblinded trials of NO in ARDS^{186,187} and were repeated in a systematic review.¹⁸⁸ In another large randomized but unblinded study of NO in ARDS, a higher proportion of patients in the NO group required renal replacement therapy than in the control group.¹⁸⁹ A meta-analysis of trials using NO for ARDS concluded that, while NO caused initial improvement in oxygenation, it had no impact on survival and was associated with an increased risk of renal dysfunction.¹⁹⁰ We suggest that NO should not be used routinely in the treatment of patients with ARDS, other than perhaps as a "rescue" therapy for extreme life-threatening hypoxemia. In fact, in a recent individual patient meta-analysis, inhaled NO did not improve mortality in patients with ARDS regardless of severity as assessed by arterial PO₂/Fio₂ ratios as low as 70.¹⁹¹

Surfactant. As discussed in the section on pathogenesis, a number of abnormalities of surfactant have been described in ARDS. These include an increase in relatively inactive forms, inactivation of surfactant by proteins that have leaked into the alveolar space, damage to type II epithelial cells (which produce surfactant), and destruction of surfactant constituents by the inflammatory process.⁴⁵ These changes, along with the efficacy of surfactant supplementation in the neonatal respiratory distress syndrome, led to the hypothesis that surfactant supplementation might be beneficial in ARDS. Data from animal studies and small case series were promising.¹⁹² A small randomized controlled trial administered bovine surfactant through an endotracheal catheter in patients with ARDS and showed in one subgroup of patients an improvement in oxygenation and a trend to decreased mortality.¹⁹³

However, enthusiasm for surfactant was greatly dampened by the results of a large multicenter randomized, blinded, placebo-controlled trial. In this study, investigators administered an aerosolized synthetic (protein-free) surfactant or saline placebo continuously for up to 5 days to patients with new onset (<48 hours) of sepsis-induced ARDS. There was no physiologic or clinical benefit from the surfactant. Despite its methodologic rigor, the study has been criticized because less than 5% of the administered dose of surfactant was thought to have reached the distal lung. In addition, the lack of surfactant proteins in the synthetic surfactant may have diminished its ability to reduce surface tension.¹⁹⁴ Because of these issues, the role of surfactant supplementation continues to be studied.

In a phase I/II trial, 40 patients with new-onset ARDS were randomized to a surfactant protein C-based preparation (given up to four times over 24 hours) or to no drug. The surfactant was administered through a catheter placed in the endotracheal tube. The drug had no effect on oxygenation or on ventilator-free days, which were the primary outcomes of the study. The authors reported a significant decrease in IL-6 levels in bronchoalveolar lavage fluid from patients who received the surfactant preparation, although it is unclear whether this was a prespecified end point.¹⁹⁵

Finally, two phase III trials of the recombinant surfactant protein C-based preparation have been completed. The studies demonstrated that the surfactant improved oxygenation, but had no impact on mortality or ventilator-free days. Only one trial, using calfactant (a natural surfactant, distinct from previous trials) in pediatric patients with ARDS, has shown any mortality benefit⁴⁶; whether this is due to the unique surfactant used in this study or to differences between the patients enrolled in this trial and the negative trials (e.g., adult vs. pediatric) is unknown. Whether surfactant will prove to be useful in well-defined subgroups of patients with ARDS remains an open question.⁴¹

Antioxidants and Anti-inflammatory Agents (Other Than Steroids). Oxidative stress has long been postulated to be involved in the pathogenesis of ARDS.⁶⁹ In fact, lung injury due to hyperoxia is a commonly used model to study ARDS in animals. Reactive oxygen species form as a by-product of activation of neutrophils and macrophages; in addition, the requirement by many patients with ARDS for a high inspired fraction of oxygen may predispose to oxidative stress. Decreased levels of glutathione, a major endogenous scavenger of reactive oxygen species, have been observed in the alveolar fluid of patients with ARDS. Small clinical trials with N-acetylcysteine and procysteine were promising.¹⁹⁶ Unfortunately, despite this optimism, larger clinical trials of antioxidants in ARDS have been disappointing. A multi-center trial of the antioxidant procysteine in ARDS showed no beneficial effect of the drug.⁴⁷

Various agents with putative anti-inflammatory effects have been tested in ARDS. These include ketoconazole, liso-fylline, and (in patients with sepsis at risk for ARDS) the nonsteroidal anti-inflammatory drug ibuprofen. In separate well-conducted, randomized, blinded, controlled trials, none of these agents demonstrated benefit in ARDS.¹⁹⁷⁻¹⁹⁹ A prospective randomized controlled trial evaluated the effect of recombinant platelet activating factor acetylhydrolase at preventing ARDS in patients with severe sepsis. This trial of more than 100 patients showed no decrease in the

development of ARDS in patients who received the drug; however, the mortality rate was lower in patients receiving an intermediate dose of the study drug.²⁰⁰ Other trials of so-called anti-inflammatory therapies in sepsis have been disappointing.^{80,171}

Novel Therapies. As discussed earlier in the section on Pathogenesis, alveolar fluid clearance can be augmented by catecholamines. A small trial randomized 40 patients with ARDS to intravenous salbutamol or placebo for 7 days.²⁰¹ Patients receiving salbutamol had a decrease in extravascular lung water but a higher incidence of arrhythmias. A follow-up study was performed in almost 50 intensive care units in the United Kingdom and enrolled more than 300 patients with ARDS. However, the trial was halted earlier than planned because of an increase in mortality in the group receiving intravenous salbutamol.⁹⁸ A similar-sized trial of aerosolized albuterol (given every 4 hours for up to 10 days) for ARDS found no benefit.²⁰² Thus, routine use of β_2 -agonists cannot be recommended in ARDS.

Stem cell therapy for ARDS is being explored.²⁰³ Beneficial effects have been noted in animals with endotracheal and intravenous delivery of stem cells²⁰⁴ and may be augmented by using stem cells transfected with ANGPT1.²⁰⁵ A schematic of novel potential therapeutic approaches is shown in Figure 100-7.

Discrepancies Between Studies in Animals and Humans. As discussed earlier, virtually all large-scale clinical trials of pharmacotherapy for ARDS have been negative, despite promising and often exciting animal studies. There are a number of reasons why results from these animal studies have not been replicated in human clinical trials. First, in animal studies, the agent being investigated is often administered at the same time or shortly after the lung is injured (e.g., cecal ligation and perforation followed by administration of the drug within a few hours). In contrast, the onset of lung injury in humans is often much more difficult to define, and potential therapies are given many hours after the diagnosis is made. Thus, agents that might have been effective at preventing or attenuating ARDS may have been given too late. Second, “proof of principle” animal studies are of relatively short duration and do not mimic the complicated clinical course of human ARDS. Third, animals in most studies represent essentially a homogeneous group; in contrast, human patients have multiple comorbidities and have multiple cointerventions. Fourth, the underlying precipitant for ARDS, even in carefully selected subgroups of patients, differ in severity and duration, unlike in animals wherein a uniform injury is applied. This heterogeneity makes it challenging to identify agents that may be of only modest clinical benefit. Finally, as discussed, the current definition of ARDS is problematic, and studies may include many patients with markedly different pathophysiology/biology.

MECHANICAL VENTILATION

Mechanical ventilation is lifesaving and is the standard therapy for ARDS. Ventilatory management of ARDS has undergone dramatic changes over the last 20 years, in large

Figure 100-7 Schematic of an alveolus depicting potential novel therapeutic strategies for ARDS. Mesenchymal stem cells have been shown to alleviate lung injury in animal models, a benefit that has been attributed to their paracrine effects. Modulation of neutrophil recruitment, activation (e.g., degranulation), and apoptosis has long been investigated as a means of preventing or abrogating lung injury, which is often considered to be neutrophil-dependent. Epithelial repair or enhancement of alveolar fluid clearance is another strategy that is being pursued, such as by up-regulation of epithelial apical sodium channels. More recently, there has been interest in increasing the integrity of the lung endothelial barrier by preventing the internalization (and loss of function) of junctional proteins such as VE-cadherin and claudin-5 or by attenuating endothelial apoptosis. Lastly (top left), clinical trials have demonstrated that certain ventilator strategies are less injurious to the lungs than others.

part due to increased use of computed tomography to image the lungs and to advance understanding of VILI.

PRESSURE AND VOLUME LIMITATION

Mechanical ventilation of patients under anesthesia for surgery traditionally involves large tidal volumes of 10 to 15 mL/kg, with the dual goals of achieving normal arterial oxygenation and arterial pH. A similar approach to ventilating patients with ARDS was followed in the past. This emphasis on achieving normal physiologic parameters in patients with ARDS was understandable at the time: in addition to being characterized by profound hypoxemia and diminished pulmonary compliance, ARDS was thought to involve the lungs diffusely and homogeneously based on plain radiography.⁷ A large tidal volume therefore appeared to be the only way to both ventilate patients and maintain oxygenation. Subsequently, studies using computed tomography²⁰⁶ demonstrated that the lungs of many patients with ARDS are actually heterogeneous: instead of the diffuse involvement suggested by plain radiographs, computed

tomography scans often show patchy opacities interspersed with more normal-appearing areas of lung (see Fig. 100-5). The heterogeneous distribution of the injury in ARDS implies that the tidal volume administered to a patient will preferentially inflate the more compliant (or normal) areas of lung. These regions of the lung, exposed to tidal volumes meant for an entire lung, are therefore at risk for overdistention and ventilator-associated lung injury. As discussed earlier, mechanical ventilation with excessive tidal volumes can cause pulmonary edema due to increased alveolar-capillary permeability, with remarkably similar histology to ARDS.

Despite the clear physiologic rationale and abundant experimental data to support pressure and volume limitation when ventilating patients with ARDS, it was not until the late 1990s that data from randomized clinical trials in humans began to accrue. Between 1998 and 2000, five randomized controlled trials of ventilation strategies in ARDS were published.^{109,160,207-209} In all of the trials, patients were randomized either to a strategy involving some degree of tidal volume and pressure limitation, or to a “conventional” ventilation strategy with higher tidal volume and pressure limits.

Of the five studies, the largest was conducted by the ARDS Network, composed of investigators from multiple American hospitals and supported by the National Heart, Lung, and Blood Institute of the United States.¹⁰⁹ This study, which was more than seven times larger than any of the other four, randomized 861 patients to lower tidal volumes or traditional tidal volumes. In the traditional group, plateau pressure was also kept below 50 cm H₂O. In the small volume group, tidal volume was set at 6 mL/kg of predicted body weight and reduced if necessary to maintain plateau pressure between 25 and 30 cm H₂O. Respiratory acidosis was treated aggressively, with the ventilator rate being set at six to 35 breaths per minute to achieve a pH of 7.3 to 7.45. Bicarbonate infusions were allowed for acidosis that persisted despite a ventilator rate of 35 breaths per minute. Tidal volume was increased for refractory acidemia, if pH was less than 7.15. Only preset combinations of PEEP and FIO₂ were allowed in the two groups, for a target oxygen saturation of 88% to 95% (Table 100-3). Patient-

ventilator dyssynchrony was reduced by sedating the patient, when necessary.

The trial, which originally set out to accrue 1000 patients, was stopped early because an interim analysis showed benefit in the small tidal volume group. The mortality rate was 39.8% in the traditional group, compared with 31% in the small tidal volume group ($P=0.007$). Breathing without assistance at day 28 was also significantly more frequent in the small volume group, and the number of ventilator-free days was higher. The number of days without organ failure was also higher in the small volume arm.

A key factor in comparing trials is to appreciate that the ARDS Network study used predicted body weight, while other studies used ideal body weight or measured body weight to set the tidal volume. The rationale underlying the use of predicted body weight is that it correlates much better with lung size than measured body weight, and the goal in individualizing the tidal volume for any patient is to match the tidal volume to the size of the lung. The distinction is important, since data from the ARDS Network study demonstrate that measured body weight was approximately 20% higher than predicted body weight. In other words, the tidal volumes used in other studies may have been higher than appreciated. Predicted body weight in kilograms can be calculated for male patients as $50 + 0.91(\text{centimeters of height} - 152.4)$, and for female patients as $45.5 + 0.91(\text{centimeters of height} - 152.4)$.¹⁰⁹

The ARDS Network study adopted an aggressive approach to hypercarbia and acidemia, including use of higher respiratory rates, bicarbonate infusions, and loosening of ventilatory restrictions. As a result, hypercarbia and subsequent low pH in the treatment arm was less marked than in some other studies. This too may have contributed to the lower mortality in the lower tidal volume arm.

Some investigators have proposed that mechanical ventilation of a given patient be set based on the static inspiratory pressure-volume curve of the patient's respiratory system.²⁰⁹ In ARDS, such curves often have a sigmoidal shape, with a lower inflection point at low lung volumes, and an upper inflection point at high volumes. Initially, it was thought that the lower inflection point represented the pressure at which collapsed lung units reexpand, accounting for the abrupt change in compliance. The upper inflection point was thought to represent the pressure at which the alveoli become overdistended. On this basis, it was proposed that PEEP should be set higher than the pressure of the lower inflection point, while plateau pressure should be kept lower than the upper inflection point. Although conceptually appealing, this interpretation of the static inspiratory pressure-volume curve is likely erroneous. Recruitment of the lung is known to continue even above the lower inflection point.²¹⁰ Conversely, during tidal ventilation, alveoli may be continually recruited so that the ventilatory cycle takes place in a region closer to the deflation limb rather on the inflation limb of the pressure-volume curve.²¹¹ Thus, limiting tidal volume or plateau pressure based on the inspiratory pressure-volume curve is not used widely.²¹²

Neuromuscular Blockade

Mechanical ventilation of patients with ARDS is often complicated by patient-ventilator dyssynchrony, which can worsen oxygenation and ventilation. To overcome this,

Table 100-3 Ventilation Protocol Used in the ARDS Network Study¹⁰⁹

Parameter	Protocol
Mode of ventilation	Volume assist control
Tidal volume	≤6 mL/kg predicted body weight*
Plateau pressure	≤30 cm H ₂ O
Frequency	6–35 breaths/min, titrated for pH 7.3–7.45
I:E ratio	1:1 to 1:3
Oxygenation goal	Arterial PO ₂ 55–80 mm Hg, or SpO ₂ 88%–95%
FIO ₂ /PEEP (cm H ₂ O)	0.3/5, 0.4/5, 0.4/8, 0.5/8, 0.5/10, 0.6/10, 0.7/10, 0.7/12, 0.7/14, 0.8/14, 0.9/14, 0.9/16, 0.9/18, 1/18–24
Weaning	By pressure support, required when FIO ₂ /PEEP ≤ 0.4/8

*See text for formula to calculate predicted body weight. I:E ratio, ratio of inspired to expired gas; SpO₂, saturation by pulse oximetry.

clinicians have traditionally sedated patients and even paralyzed them using neuromuscular blocking agents. Many clinicians have since become reluctant to use neuromuscular blocking agents because of concerns of inducing myopathy and prolonging the duration of mechanical ventilation. However, a multicenter randomized controlled trial of more than 300 patients with early (<48 hours) and severe ARDS compared a 48-hour infusion of cisatracurium to placebo.²¹³ Both groups received lung-protective ventilation based on the ARDSNet trial, discussed earlier. The authors reported a significant reduction in 90-day mortality (the primary end point) as well as a number of secondary end points, including barotrauma and organ failure. There was no increase in intensive care unit-acquired weakness. The mechanism of benefit from neuromuscular blocking agents is unknown, but may involve decreased ventilator-induced lung injury.²¹⁴ These provocative data, while promising, await replication before being widely adopted.

The Role of PEEP and Recruitment Maneuvers

As mentioned earlier, the first description of ARDS commented on the apparent utility of PEEP in improving oxygenation. From a theoretical standpoint, PEEP may be beneficial in avoiding damage from cyclic opening and closing of terminal lung units (atelectrauma, see [Pathogenesis](#)), and in allowing for a reduction in tidal volume (and hence volutrauma). In addition, PEEP, by improving oxygenation, may allow for lowering of the FiO_2 , thereby decreasing the risk for oxygen toxicity. On the other hand, PEEP that is too high can itself cause excessive end-inspiratory lung volume and volutrauma. Many clinicians are also familiar with the potential effect of PEEP to depress cardiac output and blood pressure. The optimal level of PEEP to use in patients with ARDS has therefore been a source of controversy.²¹⁵⁻²¹⁷

Along the same lines, the low tidal volumes and pressures advocated for lung-protective ventilation can lead to progressive de-recruitment of the lung, which can worsen hypoxemia and potentially aggravate atelectrauma. To counteract de-recruitment, so-called recruitment maneuvers have been proposed. These maneuvers involve an increase in airway pressure for a certain duration, although the pressure to be applied and its duration have not been standardized. One example of a recruitment maneuver would be 40 cm H_2O of continuous positive airway pressure for 40 seconds. Similar to the problems with setting the level of PEEP, however, it is difficult to predict which patients might benefit from recruitment maneuvers and which might be harmed by overdistention. Overdistention of well-perfused lung units could result in diversion of blood to poorly perfused alveoli, with consequent worsening of right-to-left shunt and hypoxemia.²¹⁸

A number of randomized controlled trials have addressed the issue of PEEP and recruitment maneuvers in the management of ARDS.

The ARDS Network investigators randomized 549 patients with ARDS to lower or higher PEEP levels, according to preset combinations of PEEP and FiO_2 . The patients in the lower PEEP arm received the PEEP/ FiO_2 levels used in the original ARDSNet trial of lung-protective ventilation (see earlier). The precise level of PEEP used in the higher

arm varied with the FiO_2 , but was on average 5 cm H_2O higher than the control arm (mean of 13 to 15 cm H_2O over the first 7 days). Recruitment maneuvers were initially used in the higher PEEP group but were discontinued after the first 80 patients because they were not very effective.²¹⁹ The study was stopped early due to perceived futility and the mortality rate in both arms was about 25%, significantly lower than had been reported in other trials of ARDS.²²⁰

A second large trial randomized almost 1000 patients with ALI to what was described as an “open lung” strategy versus the ventilation protocol used in the original ARDSNet trial.²²¹ The “open lung” strategy consisted of pressure control ventilation with plateau pressure (P_{plat}) less than 40, recruitment maneuvers, and high PEEP, together with the low tidal volumes (6 mL/kg) used in the control group. On average, on day 1 of the study, PEEP in the open lung arm was 16 cm H_2O , compared with 10 cm H_2O in the control group. This trial also found no difference in the mortality rates between the two groups (about 40%), although the open lung group had improvements in secondary end points related to hypoxemia.

Finally, a large French trial randomized 767 patients with ALI to PEEP of 5 to 9 cm H_2O or PEEP maximized as long as P_{plat} was less than 28 to 30.²²² On day 1 of the study, the mean applied PEEP level in the control arm was about 7 cm H_2O , or marginally lower than that of patients in the original ARDSNet trial of lung-protective ventilation, while the higher PEEP arm had an average applied PEEP of 15 cm H_2O . The study demonstrated no difference in mortality, but the higher PEEP arm had improved compliance, oxygenation, and a decreased duration of mechanical ventilation and organ failure.²²²

Taken together, the data from these trials suggest that higher PEEP levels than used in the original ARDSNet trial are safe and may improve oxygenation, but there are insufficient data to argue that higher PEEP improves survival. Why these clinical studies are generally negative despite very strong animal data demonstrating the benefits of higher PEEP levels is somewhat of a puzzle. One possibility is the yin-yang of PEEP. To the extent that PEEP recruits lung units, it may be beneficial; to the extent that it leads to greater overdistention of lung units, it may be harmful. In all studies to date, PEEP has been applied to all patients whether or not their lungs are recruitable. As such, one reasonable approach to be tested in future studies of PEEP is to randomize only patients to a high/low PEEP strategy if they have lungs that are potentially recruitable.^{217,223} Indeed, a meta-analysis that included these trials found that while higher PEEP was associated with a lower mortality in patients with arterial $\text{PO}_2/\text{FiO}_2 < 200$ mm Hg (i.e., ARDS), there was less benefit and a trend to harm in patients with a higher arterial PO_2/FiO_2 and hence less severe lung injury.²²⁴

The data also suggest that the role of recruitment maneuvers in the management of ARDS is only supportive, and the data currently available do not demonstrate improvement in clinically important outcomes. The major putative benefit of recruitment maneuvers is to decrease ventilator-induced lung injury. Many studies report a variable and transient improvement in oxygenation after some form of recruitment,²¹⁹ which can be better maintained with a higher level of PEEP after recruitment. It is also possible that the same degree of recruitment could be achieved by

simply raising the level of PEEP.^{225,226} Although recruitment maneuvers are generally safe, the patient must be closely monitored for any adverse effects on hemodynamics or oxygenation.

Permissive Hypercapnia and Tracheal Gas Insufflation

The use of lower tidal volumes (to avoid VILI) often results in respiratory acidemia, an effect that has been termed *permissive hypercapnia*. The theoretical detrimental effects of hypercapnia include myocardial depression, increased pulmonary vascular resistance, and decreased renal blood flow. Hypercapnia may have an injurious effect on alveolar epithelial cells.²²⁷ Perhaps the most clinically important adverse effect of hypercapnia is elevated intracranial pressure from increased cerebral blood flow. However, data also suggest that hypercapnia has protective effects, including attenuation of free radical-mediated lung injury and pulmonary inflammation.^{228,229}

Given the uncertainty about permissive hypercapnia, it is worth remembering that the only large randomized controlled trial to show a reduction in mortality in ARDS treated respiratory acidosis fairly aggressively (discussed earlier).¹⁰⁹ In the absence of other data, following the protocol used in that study seems prudent.

One approach that has been used to decrease high levels of arterial PCO₂ is tracheal gas insufflation, a technique whereby a gas flow is introduced via a small catheter placed in the endotracheal tube, with its tip near the carina. Tracheal gas insufflation has been proposed as an adjunct to permissive hypercapnia, because the insufflated gas improves CO₂ clearance from the anatomic dead space and ventilator tubing. However, the gas flow has the potential to increase alveolar volume and pressure, and may increase PEEP.²³⁰ Although there are many case reports describing the use of tracheal gas insufflation,²³¹ there have been no randomized studies in ARDS. Because of technical and monitoring issues, we do not recommend its routine use of tracheal gas insufflation in ARDS.

Mechanical Ventilation of Patients in the Prone Position (Proning)

Placing patients with ARDS in the prone position (proning) was described almost 30 years ago as a means of improving oxygenation. The mechanisms by which the prone position improves oxygenation are multiple, but probably the most important factor is the effect that proning has on chest wall and lung compliance.²³² In the supine position, the most dorsal and caudal regions of lung (along the spine and diaphragm) are the worst affected in many patients with ARDS. Some of this is due to gravity, but the weight of the heart and of the abdominal organs on the lungs also contributes. When a patient is placed in the prone position, the anterior chest wall is fixed (by the bed) and becomes less compliant, thus increasing the proportion of ventilation directed to the dorsal lung. In addition, the volume of lung that is being compressed by the heart due to gravity is substantially decreased. The net result is more homogenous ventilation of the lung and presumably improved \dot{V}/\dot{Q} matching. Data from a study in dogs suggest that ventilation in the prone position can attenuate the severity of VILI.²³³

A number of multicenter randomized controlled trials have now examined the efficacy of proning in patients with ARDS. One study enrolled more than 300 patients with ALI and randomized them to conventional treatment (supine) or treatment in the prone position for 6 or more hours for 10 days. The study found that oxygenation improved in approximately 70% of proning procedures and that most of the improvement was evident within 1 hour of proning. However, although oxygenation improved significantly in prone patients, there was no difference in mortality between the groups. Retrospective analyses of the quartile of patients with the poorest oxygenation or the highest acuity of illness (or the highest tidal volume) showed a lower mortality rate at 10 days in the patients who were prone, but this difference did not persist beyond discharge from the intensive care unit.²³⁴ The study has been criticized for the relative short duration of the intervention, as well as the fact that most patients spent the majority of the day supine.²³⁵

A subsequent study randomized more than 700 patients with acute hypoxemic respiratory failure (which included but was not limited to patients with ARDS) to ventilation in the prone or supine position; patients were prone an average of 50 hours after intubation for a median of 8 hours per day, for a median of 4 days.²³⁶ Prone patients exhibited improved oxygenation but no improvement in mortality or duration of ventilation. These patients also suffered from a higher incidence of complications, including pressure sores, selective intubation, and endotracheal tube obstruction.

A pediatric study (median age 2 years) of proning in ARDS was similarly negative,²³⁷ and two Spanish trials of proning for adults with ARDS were inconclusive but suggestive of benefit.^{238,239}

In 2013, a multicenter randomized trial of prolonged (>16 hours) proning was reported in more than 400 patients with early (<36 hours) and severe ARDS.²⁴⁰ ARDS was defined according to the AECC criteria, with severe ARDS denoting arterial PO₂/FIO₂ < 150 mm Hg with FIO₂ ≥ 0.6, PEEP ≥ 5 cm H₂O and tidal volume of about 6 mL/kg predicted body weight. Patients were prone within the first hour after randomization and kept prone for at least 16 consecutive hours; proning was performed every day up to day 28. Remarkably, the 28-day survival rate was 16% in the prone group and 33% in the supine group.

These results are very impressive and are likely to increase the adoption of proning by intensivists. While proning in that trial was not associated with any complications, it is important to note that it was conducted in centers with significant expertise in prone-position ventilation, which requires some attention to detail, and that it did not involve use of a rotating bed. Lines and tubes are vulnerable to dislodgement during the process, and sufficient staff should be on hand to assist with the move. Personnel should be ready and capable of immediate reintubation in case the endotracheal tube is displaced. Prone patients are more susceptible to development of pressure sores, and exquisite care must be taken to ensure that no stray objects (e.g., syringes, electrocardiogram leads) are left under the patient, because these leave impressions and even scars on the body. An unstable spinal injury is an absolute contraindication to proning. In addition, if cardiopulmonary resuscitation is required, the patient must be returned to the supine

position emergently. Finally, in the most recent trial, there were a number of exclusion criteria, including elevated intracranial pressure, massive hemoptysis, recent tracheal or facial surgery, and low mean arterial pressure (<65 mm Hg).²⁴⁰

Volume-Control Versus Pressure-Control Ventilation

The volume and pressure-limited protocol used in the ARDS Network study employed volume-assist control as the mode of ventilation. The Lung Open Ventilation study (described earlier) demonstrated that pressure-control ventilation could be used with equivalent outcomes.²²¹ Other studies that have examined this issue have also found little difference in physiologic parameters or outcome between the two modes of ventilation.^{241,242}

High-Frequency Jet Ventilation and High-Frequency Oscillation

In high-frequency jet ventilation, a small gauge catheter is used to introduce gas under high pressure into the endotracheal tube. The high velocity of the gas entrains additional oxygen and humidified air from side ports in the system. This form of mechanical ventilation achieves a tidal volume of 2 to 5 mL/kg and involves frequencies of 100 to 200 breaths per minute.²⁴³ Exhalation is passive, requiring recoil of the lungs and chest wall. There is little evidence that high-frequency jet ventilation is superior to conventional mechanical ventilation for ARDS. An early randomized trial of over 300 oncology patients with ARDS compared conventional ventilation (using volume-cycled ventilation) with high-frequency jet ventilation. Because the end points of the study differed between the two groups of patients, it is difficult to interpret the data. Nonetheless, the authors found no significant difference in any clinically important outcome.²⁴⁴

In *high-frequency oscillatory ventilation* (HFO), lung recruitment is maintained using a constant mean airway pressure generated by an inspiratory bias flow and limitation of gas outflow from the circuit. Ventilation is achieved through rapid (e.g., 5 Hz) regular oscillations of a piston or diaphragm. The push and pull action of the piston causes oscillations in pressure in the endotracheal tube and proximal airways, creating peak and trough pressures around the set mean airway pressure. The tidal volumes achieved through HFO are small, on the order of 1 to 5 mL/kg. In theory, HFO seems ideally suited for avoiding VILI. Atelectrauma is minimized because of the relatively high mean airway pressure, which along with small tidal volumes limits derecruitment of the lung, and volutrauma is minimized because the small tidal volumes limit end-inspiratory stretch.²⁴⁵ With HFO, loss of pressure from the circuit can lead to de-recruitment, thus recruitment maneuvers (e.g., application of continuous positive airway pressure for approximately 30 to 40 seconds) should be applied after each patient disconnect from the ventilator (e.g., open suctioning).

In an early randomized trial of HFO in adults, 148 patients with ARDS were randomized to conventional ventilation using pressure-control mode or to HFO.²⁴⁶ The specific ventilatory parameters for both the conventional group and the HFO group were adjusted to achieve adequate

oxygenation at a minimum FiO_2 (i.e., 88% at $\text{FiO}_2 \leq 0.60$), as well as an arterial pH greater than 7.15. Because the study was begun before the publication of the ARDS Network trial on tidal volume limitation, the conventional ventilation arm of this study targeted tidal volumes of 6 to 10 mL/kg. The trial was not powered to detect a mortality difference, and there was no significant difference in 30- or 90-day mortality, or in any other outcome. The authors performed a retrospective analysis of predictors of mortality, and discovered that being on conventional ventilation for more than 5 days correlated with a poor outcome.

More recently, two large randomized trials of HFO were published and showed no benefit in terms of survival or the duration of mechanical ventilation^{247,248} compared with conventional lung-protective ventilation. Indeed, one of the studies suggested that HFO might be harmful due to the amount of sedation required or due to impairment of hemodynamics. Because of these findings, the routine use of HFO for ARDS cannot be recommended, although its role as “rescue” therapy is not clear.

Liquid Ventilation

Liquid ventilation relies on the oxygen and carbon dioxide carrying capacity of organic liquids such as perfluorocarbons. Perfluorocarbons are modified hydrocarbons in which hydrogen atoms are replaced with fluorine, generating inert liquids that are nontoxic and minimally absorbed through the respiratory epithelium. The most widely studied perfluorocarbon, perflubron (perfluorooctyl bromide, [eFig. 100-2](#)), can dissolve about 17 times more O_2 than saline solution and almost 4 times more CO_2 .²⁴⁹ Total liquid ventilation is a technique in which the lungs are completely filled with liquid and an extracorporeal exchanger is used to add O_2 and remove CO_2 from the liquid. Partial liquid ventilation, which is much easier to use clinically, involves partially filling the lung with liquid and then using a traditional ventilator to deliver gas tidal volumes.²⁵⁰

The theoretical benefits of liquid ventilation stem largely from improved lung recruitment, due to the lower surface tension of the perfluorocarbons and because the liquid tends to distribute to the dependent regions of the lung. Deposition of liquid with low surface tension in these areas may enhance alveolar recruitment; in addition, the weight of the liquid is thought to cause diversion of pulmonary blood flow to the nondependent (better ventilated) areas, improving \dot{V}/\dot{Q} matching. Clearance of secretions (due to their displacement by the liquid) is also improved. Anti-inflammatory effects of perflubron have been described, although the clinical relevance of these effects is not well understood. To date, two randomized controlled trials of partial liquid ventilation in adults with ARDS have been published.²⁵¹ The first enrolled 90 patients with ARDS to partial liquid ventilation with perflubron or to conventional mechanical ventilation. Other than very general guidelines (e.g., target arterial $\text{SO}_2 > 90\%$), neither of the two ventilation strategies was protocolized. In addition, the inclusion and exclusion criteria were modified slightly during the course of the study. There was no significant difference in the number of ventilator-free days (the primary outcome measure) or in any other predefined outcome. More patients in the liquid ventilation arm experienced hypoxia, bradycardia, and respiratory acidosis, although the increase in

the incidence of these adverse events was not statistically significant.

In 2006 a multicenter randomized trial of partial liquid ventilation with perfluorocarbon compared with conventional mechanical ventilation (VT 10 mL/kg) enrolled more than 300 patients with ARDS. The study found a trend toward higher mortality in the groups receiving perfluorocarbon in addition to a higher incidence of barotrauma, hypoxia, and hypotension.²⁵² Based on these data, partial liquid ventilation cannot be recommended for patients with ARDS.

Extracorporeal Membrane

Oxygenation (see Chapter 103)

Extracorporeal membrane oxygenation (ECMO), also referred to as extracorporeal life support or extracorporeal lung assist, refers to the process by which the patient's blood is circulated to an external machine that provides oxygenation and/or carbon dioxide removal.²⁵³ In theory, ECMO could be used to oxygenate patients with ARDS while minimizing VILI and oxygen toxicity and allowing the lungs time to heal. There are multiple case reports of ECMO being used in ARDS, and it is used routinely in neonates with severe respiratory failure. A randomized controlled trial of ECMO in ARDS was completed almost 30 years ago and did not show any benefit.²⁵⁴ It is worth pointing out that the mortality rate in that study was approximately 90% in both the ECMO and the control arm. Subsequently, a variant of ECMO dedicated to carbon dioxide removal (extracorporeal CO₂ removal, or ECCO₂R) was developed and showed promise in a case series when compared with a historical control group.²⁵⁵ This was followed by a randomized controlled trial using pressure-controlled *inverse-ratio ventilation* (IRV) and ECCO₂R in ARDS that failed to find any improvement in survival.²⁵⁶ This study illustrates the importance of using concurrent controls when assessing a novel therapy.

One of the complications of ECMO is bleeding; in an early randomized trial, patients randomized to the device were transfused an average of 1.7 L of blood *per day*. More recent data suggest that, because of many technological improvements, ECMO can be relatively safely performed by specialized centers. In 2009, a randomized controlled trial of conventional ventilation versus ECMO for acute respiratory failure was reported.²⁵⁷ The vast majority of patients in each arm had ARDS; referral to an ECMO center conferred a statistically significant survival benefit (relative risk of death at 6 months, 0.69; confidence interval, 0.05–0.97). However, patients in the conventional ventilation arm were cared for in multiple hospitals, did not have a standardized ventilation protocol, and experienced a mortality rate of 53%. In contrast, of the patients referred to the ECMO center, 75% actually received ECMO and a significantly higher percentage of patients in this group received lung-protective ventilation. Thus, it is unclear whether the improvement in survival was attributable to ECMO or to better care in a specialized hospital. A cohort study by the same authors examining ECMO for H1N1 influenza-induced ALI also suggested lower mortality from the treatment.²⁵⁸

There is also growing interest in using extracorporeal life support as an adjunctive therapy to maximize the benefit of lung-protective ventilation. Even at the recommended tidal

volume of 6 mg/kg, the lungs of patients with ARDS may be damaged by overdistention and VILI. Thus, the promise of ECMO is that tidal volumes of less than 6 mL/kg predicted body weight can be used and the resultant respiratory acidosis can be managed by extracorporeal removal of CO₂.²⁵⁹ Because of ongoing technological improvements that have reduced the requirement for anticoagulation and the invasiveness of the devices,^{260,261} this is likely to be a fertile area of research in coming years.

Summary

The modern approach to mechanical ventilation of patients with ARDS is based on two facts: first, that the diffuse lung injury of ARDS affects the lung heterogeneously; second, that mechanical ventilation itself can cause ALI. Thus, until new data emerge, the lung-protective ventilatory strategy adopted by the ARDS Network study¹⁰⁹ is the standard of care and is associated with both short-term and long-term improvement²⁶² in survival. Plateau pressure should be maintained at less than 30 cm H₂O, and tidal volume should be limited to 6 mL/kg predicted body weight as much as possible. The prone position should be seriously considered in patients with P/F less than approximately 150 mm Hg in centers with medical staff experienced in proning patients. Given the dangers inherent in this approach, proning must be performed with caution and following published protocols.

The optimal level of PEEP in ARDS remains unclear, although randomized trial data indicate that using higher PEEP levels than the original ARDS Network study is safe and may improve oxygenation. We favor high levels of PEEP in order to prevent atelectrauma, reduce FIO₂ and prevent hyperoxic lung injury in patients with greater hypoxemia (i.e., P/F < approximately 150 mm Hg), as long as the patient's hemodynamic status remains stable. We use the lowest possible FIO₂ that maintains oxygen saturation above 90%, and we empirically adopt a target FIO₂ of less than 0.6.

The use of neuromuscular blocking agents may also improve outcome by reducing ventilator-induced lung injury when used early in the clinical course of patients with relatively severe ARDS. Finally, despite the theoretical appeal of HFO ventilation, randomized controlled trials have shown that it does not improve survival over conventional lung-protective ventilation.

LONG-TERM OUTCOMES

Despite the profound derangement in oxygenation and respiratory system compliance that is characteristic of ARDS, it is remarkable that patients who survive often have near-normal pulmonary function tests 6 to 12 months later. Lung volumes and flows are generally slightly reduced or normal at 6 to 12 months, while the diffusion capacity may remain slightly reduced.^{263,264} Follow-up chest radiographs are usually normal, with a minority showing subtle abnormalities including pleural thickening or small cysts.²⁶⁴

Despite this impressive physiologic and radiologic recovery, patients who survive ARDS continue to have important functional limitations and a decreased health-related quality of life for at least 5 years after their illness.^{265,266} This reduction in quality of life seems attributable to ARDS or to

its management or complications because, in one parallel cohort study in which patients with ARDS were matched with patients with sepsis or trauma with an equivalent severity of illness, the ARDS survivors reported significant decrements in health-related quality of life, particularly as related to physical function and pulmonary symptoms.²⁶⁷ This reduced quality of life (in areas reflecting physical function) has been correlated with the presence of persistent abnormalities in pulmonary function tests.²⁶³ In other patients, functional capacity (as measured by a 6-minute walk test) was persistently reduced and was ascribed to persistent muscle weakness and wasting.²⁶⁴ In a multivariate analysis in that study, better functional capacity was associated with a lack of systemic corticosteroid administration, absence of illness acquired in the intensive care unit, and rapid resolution of lung injury and multiorgan dysfunction. Patients who ultimately survive an episode of ARDS do *not* appear, however, to have increased mortality compared with other, similarly ill intensive care unit survivors.²⁶⁸

Psychological problems, including depressive symptoms,²⁶⁹ have been described in survivors of ARDS. In a retrospective case-control study, survivors of ARDS were found to have significantly more signs and symptoms of posttraumatic stress disorder than patients who had undergone maxillofacial (and presumably elective) surgery; they also had more signs and symptoms of posttraumatic stress disorder than soldiers who had served for prolonged periods of time in Bosnia.²⁷⁰ Persistent cognitive impairment has also been observed in survivors of ARDS for as long as 1 year after hospital discharge.²⁷¹ Most patients in this study had impairments in at least one of memory, concentration, attention, or mental processing speed. Interestingly, these abnormalities were correlated to the degree and duration of hypoxemia of the patients.

ARDS is, by definition, a syndrome caused by a heterogeneous group of insults and is not a specific diagnosis. In particular, the clinician must search for an underlying cause to begin appropriate therapy. What has changed in the past 20 years, however, is our realization that in ARDS, regardless of the precipitant, inappropriate mechanical ventilation can do more harm than good. Amidst all the heterogeneity that is ARDS, it is perhaps ironic that this potential for iatrogenic injury may turn out to be one of the few common elements.

Key Points

- ARDS is a syndrome defined by acute hypoxemia, bilateral opacities on chest radiograph, and the absence of left atrial hypertension.
- The pathogenesis of ARDS is not clear, but increased permeability of the alveolar-capillary membrane due

to neutrophilic infiltration of the lungs is thought to be an important factor.

- ARDS is a syndrome, not a specific diagnosis; clinicians must, therefore, look for the cause in order to institute specific therapy.
- The mortality rate for ARDS has fallen since the 1980s and is now less than 40%.
- Mechanical ventilation is lifesaving but, when inappropriately applied, can induce or aggravate lung injury.
- Most deaths in patients with ARDS are from multiorgan failure rather than hypoxia per se.
- No pharmacologic therapies have been shown to improve survival in ARDS; thus, management consists of treating the underlying cause, lung-protective ventilation, conservative management of fluids, and excellent supportive care.
- Many survivors of ARDS suffer from a reduced quality of life and cognitive impairment.
